111. Berde CB, Lehn BM, Yee JD, et al: patient-controlled analgesia in children and adolescents: a randomized, prospective comparison with intramuscular administration of morphine for postoperative analgesia. *J Pediatr* 118(3):460–466, 1991.

This randomized prospective comparison of morphine patient-controlled analgesia (PCA) and PCA with continuous morphine infusion found that PCA is a safe and effective method of postoperative pain relief in children and adolescents.

114. Anghelescu DL, Faughnan LG, Oakes LL, et al: Parent-controlled PCA for pain management in pediatric oncology: is it safe? *J Pediatr Hematol Oncol* 34(6):416–420, 2012.

This retrospective review of self-administered patient-controlled analgesia (PCA), nurse-controlled PCA, and parent-controlled PCA found that parent-controlled PCA by authorized parents was as safe as the other methods of PCA administration.

149. Wong R, Wiffen PJ: Bisphosphonates for the relief of pain secondary to bone metastases. *Cochrane Database Syst Rev* (2):CD002068, 2002.

This Cochrane review of 30 randomized controlled studies found evidence supporting the use of bisphosphonates for relief of pain from bone metastases and recommended that bisphosphonates be considered, particularly when analgesics or radiotherapy provide inadequate pain control.

159. Smith EM, Pang H, Cirrincione C, et al: Effect of duloxetine on pain, function, and quality of life among patients with chemotherapy-induced painful peripheral neuropathy: a randomized clinical trial. *JAMA* 309(13):1359–1367, 2013.

In this multicenter, randomized, double-blind, placebo-controlled crossover trial it was found that duloxetine therapy resulted in decreased pain in adults who had chemotherapy-induced peripheral neuropathy.

177. Greco C, Berde C: Pain management for the hospitalized pediatric patient. *Pediatr Clin North Am* 52:995–1027, 2005.

This article provides a comprehensive review of pain assessment and treatment in hospitalized children.

215. Bloechl-Daum B, Deuson RR, Mavros P, et al: Delayed nausea and vomiting continue to reduce patients' quality of life after highly and moderately emetogenic chemotherapy despite antiemetic treatment. *J Clin Oncol* 24(27):4472–4478, 2006.

In this study, a multicenter prospective evaluation of adults receiving highly or moderately emetogenic chemotherapy, it was found that even with modern antiemetic therapy, more than half of patients experienced delayed nausea, and that of the adults who did not experience nausea and vomiting during the first 24 hours, 23% experienced delayed nausea and vomiting that affected daily life. Nausea had a stronger negative impact on patients than did vomiting.

224. Tyc VL, Mulhern RK, Barclay DR, et al: Variables associated with anticipatory nausea and vomiting in pediatric cancer patients receiving ondansetron antiemetic therapy. *J Pediatr Psychol* 22(1):45–58, 1997.

This study is one of the few studies to examine anticipatory nausea and vomiting in children with cancer. Children expecting severe postchemotherapy vomiting and those more distressed by nausea and vomiting were more likely to experience anticipatory nausea and vomiting.

248. Mizukami N, Yamauchi M, Koike K, et al: Olanzapine for the prevention of chemotherapy-induced nausea and vomiting in patients receiving highly or moderately emetogenic chemotherapy: a randomized, double-blind, placebo-controlled study. *J Pain Symptom Manage* 47(3):542–550, 2014.

This randomized, double-blind, placebo-controlled trial of adults receiving highly or moderately emetogenic chemotherapy and antiemetic therapy with a 5-hydroxytryptamine 3 receptor antagonist, steroid, and neurokinin-1 receptor antagonist compared patients who also received 5 mg/day olanzapine with patients who received placebo. The olanzapine group reported a higher rate of total control of vomiting, less nausea, and higher quality of life.

294. Basch E, Prestrud AA, Hesketh PJ, et al: Antiemetics: American Society of Clinical Oncology clinical practice guideline update. *J Clin Oncol* 29(31):4189–4198, 2011.

This update to the American Society of Clinical Oncology clinical practice guidelines, although not specific to the pediatric population, addresses equivalency of the neurokinin-1 receptor antagonists fosaprepitant and aprepitant and includes recommendations regarding selection of 5-hydroxytryptamine 3 receptor antagonists and management of patients undergoing radiation therapy with a high risk of emesis.

324. McCrea JB, Majumdar AK, Goldberg MR, et al: Effects of the neurokinin1 receptor antagonist aprepitant on the pharmacokinetics of dexamethasone and methylprednisolone. *Clin Pharmacol Ther* 74(1):17–24, 2003.

This study evaluated the effect of coadministration of aprepitant with dexamethasone or methylprednisolone and determined that aprepitant resulted in increased plasma concentrations of both corticosteroids, suggesting that in the setting of coadministration with aprepitant, the corticosteroid dose should be decreased.

327. de Wit R, Herrstedt J, Rapoport B, et al: Addition of the oral NK1 antagonist aprepitant to standard antiemetics provides protection against nausea and vomiting during multiple cycles of cisplatin-based chemotherapy. *J Clin Oncol* 21(22):4105–4111, 2003.

Given the concern that patients receiving cisplatin-based chemotherapy are at risk for a decreased response rate after repeated cycles of chemotherapy, this study evaluated patients who received aprepitant in addition to a standard antiemetic regimen. Study results indicate that patients who received aprepitant had better and more sustained protection against chemotherapy-induced nausea and vomiting over the course of multiple cycles.

410. Yuan CS, Foss JF, O'Connor M, et al: Methylnaltrexone for reversal of constipation due to chronic methadone use: a randomized controlled trial. *JAMA* 283(3):367–372, 2000.

This randomized controlled trial was one of the first to demonstrate that methylnaltrexone can reverse opioid-associated constipation. Administration of intravenous methylnaltrexone induced laxation and reversed the slowing of oral cecal–transit time by opioids.

456. Vogelzang NJ, Breitbart W, Cella D, et al: Patient, caregiver, and oncologist perceptions of cancer-related fatigue: results of a tripart assessment survey. The Fatigue Coalition. *Semin Hematol* 34(3 Suppl 2):4–12, 1997.

This survey-based study demonstrates the need for increased oncologist awareness and appreciation of the impact of cancer-related fatigue on patients. Despite its impact, patients often do not discuss fatigue with their oncologist and believe it is a symptom to be endured. This study highlights the multiple opportunities that may exist for improving care for patients with cancer-related fatigue.

458. Curt GA, Breitbart W, Cella D, et al: Impact of cancer-related fatigue on the lives of patients: new findings from the Fatigue Coalition. *Oncologist* 5(5):353–360, 2000.

This study describes the prevalence and impact of fatigue on adults, including its emotional, social, physical, and economic impact on patients with cancer and their caregivers.

495. Yee JD, Berde CB: Dextroamphetamine or methylphenidate as adjuvants to opioid analgesia for adolescents with cancer. *J Pain Symptom Manage* 9(2):122–125, 1994.

This case series describes the use of psychostimulants to counteract opioid-associated analgesia in children with cancer. The findings were encouraging, and future prospective controlled studies are needed to assess the efficacy and safety of stimulants for this indication.

547. Pao M, Ballard ED, Rosenstein DL, et al: Psychotropic medication use in pediatric patients with cancer. *Arch Pediatr Adolesc Med* 160(8):818–822, 2006.

In this retrospective review of children receiving cancer care it was found that psychotropic medications are commonly prescribed. The review calls attention to the need for trials to evaluate the safety and efficacy of these agents in children with complex medical illness who are experiencing mood disturbance and anxiety.

CHAPTER 72

Childhood Cancer Survivorship

Lynda Vrooman, Lisa Diller, and **Lisa B. Kenney**

CHAPTER OUTLINE

HISTORY AND OVERVIEW
Recognition of Late Effects
Early Mortality
Identifying Risk Factors for Late Effects
Interpreting Late Effects Research
General Principles of Late Effects
SECOND CANCERS
Secondary Solid Tumors
Hematologic Malignancies
ORGAN SYSTEM LATE EFFECTS
Cardiovascular System
Pulmonary System
Endocrine System
Central Nervous System
Reproductive System
Renal System
Genitourinary System
Gastrointestinal System
OTHER LATE EFFECTS
Infections
Dental Problems
Psychosocial Function
SPECIAL CONSIDERATIONS FOR THE HEMATOPOIETIC STEM CELL TRANSPLANT SURVIVOR
FOLLOW-UP CARE OF CHILDHOOD CANCER SURVIVORS
Models of Survivorship Care
Comprehensive Clinical Evaluation
FUTURE DIRECTIONS

With ongoing advances in the diagnosis and treatment of childhood cancers, increasing numbers of children and adolescents diagnosed with cancer are becoming long-term survivors. However, even as higher cure rates are achieved, there is increasing recognition that the diagnosis and treatment of cancer during childhood and adolescence can have lifelong implications for health and well-being. Cancer therapy administered during critical periods of growth and development render childhood cancer survivors vulnerable to a variety of physical and emotional disorders often referred to as “late effects.” Some late effects can be diagnosed soon after completion of cancer-directed therapy, and others may not manifest until decades later. The severity of late effects ranges from minor disabilities to chronic conditions and even life-threatening morbidities, including second cancers, cardiac disease, and pulmonary dysfunction. Severe late effects can reduce a survivor’s life expectancy.

Although remarkable progress has been made in advancing our understanding of the adverse health outcomes associated with treatment of childhood cancer, survivors continue to experience significant long-term morbidity related to late effects. Increasingly it is recognized that the care of the child or adolescent diagnosed with cancer does not end with the completion of therapy but continues on the path into adulthood. Clinical focus during survivorship care shifts from treatment of the primary cancer and screening for its recurrence to the prevention, detection, and management of adverse consequences of prior therapy. Ultimately, ongoing research may result in the reduction or even elimination of late effects and in improved quality of life for childhood cancer survivors.

HISTORY AND OVERVIEW

Prior to 1950, children and adolescents who developed cancer rarely survived. The first generation of survivors primarily consisted of children with Hodgkin lymphoma, sarcoma, and Wilms tumor who were successfully treated with surgery and high-dose, large-field radiation therapy.[1-4] The widespread use of multiagent chemotherapy, beginning in the 1970s, resulted in dramatic increases in survival for the most common childhood cancer, acute

leukemia, and continued improvement in survival for other pediatric cancers as well.[5] By the mid-1970s, many forms of childhood cancer became treatable, and potentially curable. Continuing advances in treatment options for childhood cancer have continued to improved survival. Children with cancer have also benefited from improvements in diagnostic testing, resulting in earlier and more precise diagnosis and more timely delivery of necessary treatment. Enhanced supportive care including advances in intensive care, blood banking, and management of infectious disease and acute toxicities of therapy also contributed to successful outcomes. Currently, the overall 5-year survival for childhood cancer exceeds 80%, and for some cancer diagnoses 5-year survival is above 95% (Fig. 72-1).[6] There are estimated to be more than 300,000 adult survivors of childhood cancer in the U.S. population, and this number continues to grow by approximately 10,000 survivors each year.[7]

Recognition of Late Effects

Along with these remarkable advances in survival there is a growing recognition that treatment for childhood cancer is associated with long-term complications or “late effects.” Late effects can be defined as adverse health outcomes experienced by childhood cancer survivors associated with previous cancer–directed therapy; these outcomes reduce survival or affect the “quality” of survival. Some late effects can be life threatening and contribute to the increased risk for early mortality observed in adults who are long-term survivors of childhood cancer. Other late effects, such as neurocognitive impairment, physical deformity, and infertility, can limit survivors’ social or economic opportunities and impair their overall quality of life. In contrast, some late effects may be “positive” effects, such as increase in psychological resiliency and decrease in smoking rates and the rates of other high-risk behaviors compared with those in the rest of the population.[8,9]

Second cancers, cardiopulmonary disease, and infertility were among the first treatment-associated late effects recognized in childhood cancer survivors. These first descriptions were based on clinical observations in small numbers of the earliest survivors of childhood cancer treated primarily with surgery and irradiation in the 1960s.[10-12] Early clinical observations created awareness about late effects and identified the need for further research defining treatment-related health outcomes in the growing numbers of survivors of childhood cancer.

Early Mortality

Follow-up studies of the earliest cohorts led to the observation that childhood cancer survivors are at risk for early mortality. These studies showed that late recurrence of the primary cancer and treatment-associated complications resulted in decreased long-term survival, 80% at 20 years after diagnosis compared with 97% expected survival in the age-matched general population.[13,14] The majority of premature deaths observed in survivors in these early studies were attributed to late relapse, whereas treatment-associated second cancers and major organ toxicity accounted for 30% of deaths.[13-16] It was also recognized that the risk for dying of a treatment-related cause increased with increasing intensity of therapy.[15,16] Although late recurrence accounts for the majority of premature deaths observed in childhood cancer survivors, the risk for relapse diminishes over time while the risk for therapy-related mortality persists beyond 25 years of follow-up.[17-21] Figure 72-2 depicts all-cause mortality in 5-year survivors of childhood cancer, and Figure 72-3 demonstrates all-cause mortality by underlying cancer diagnosis.[21] It remains to be determined if current treatment protocols that are specifically designed to reduce late effects will continue to improve very long-term survival by reducing the risk for therapy-related mortality.

Identifying Risk Factors for Late Effects

After the early descriptive studies, registry-based investigations of larger groups of childhood cancer survivors were undertaken with the aim of identifying specific risk factors for late effects. These included the National Cancer Institute’s “Five Center Study,” a registry-based cohort that enrolled 2490 adult 5-year survivors diagnosed with cancer between 1945 and 1975 at age younger than 20 years who were followed prospectively for reproductive outcomes, second cancers, and mortality[22]; the “Late Effects Study Group,” a multiinstitutional cohort that analyzed the occurrence of second cancers in 9170

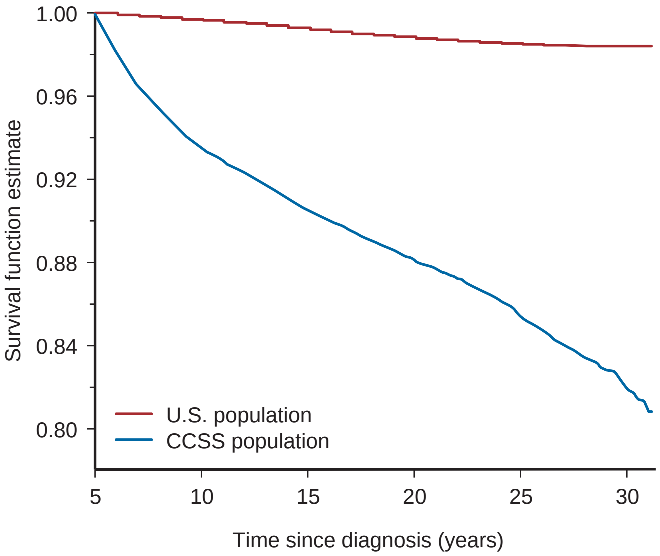

Figure 72-2 All-cause mortality in 5-year survivors of childhood cancer diagnosed from 1970 to 1986, age younger than 21 years. *(From Armstrong GT, Liu Q, Yasui Y, et al: Late mortality among 5-year survivors of childhood cancer: a summary from the Childhood Cancer Survivor Study.* J Clin Oncol *27:2328–2338, 2009).*

two-year survivors of childhood cancer diagnosed between 1936 and 1979[23]; and cancer registry–based studies in the United Kingdom,[24] the Netherlands,[25] and the Nordic countries (Denmark, Finland, Iceland, Norway, Sweden)[26] from the same early treatment era and beyond. These epidemiologic studies analyzed the association between specific treatments and adverse health outcomes of interest. Relative risks were calculated to compare rates of outcomes under study in cancer survivors with rates in a control population. Collectively these investigations made significant contributions to the understanding of late effects. Limitations of such studies of late-occurring outcomes included that recruitment was often not complete, resulting in a possible overrepresentation of childhood cancer survivors who were experiencing health conditions related to their prior therapy. In addition, some of the late effects observed in these cohorts were associated with historic treatments that have been replaced by more modern modalities. However, despite such limitations, these studies identified the relationships, now well accepted, between cancer therapy and early mortality, radiation therapy and secondary cancers, and alkylating agents and gonadal dysfunction.[16,22,27,28]

To address the limitations of prior studies, the development of "survivor" cohorts to be followed prospectively was undertaken by investigators in North America and Europe. In North America, a multiinstitutional follow-up study of a cohort of over 14,000 childhood cancer survivors (the Childhood Cancer Survivor Study [CCSS]) was created, evaluating late effects in survivors diagnosed from 1970 to1986, at age younger than 21 years, and surviving at least 5 years from diagnosis.[29] A recent expansion of the CCSS to include survivors treated between 1986 and 1999 will yield important analyses of the effects of more "modern" therapies, as well as reflect a more ethnically and racially diverse population in North America.[30] The CCSS uses self-reported questionnaires to obtain health outcomes and analyzes the association between outcome and treatment variables documented in abstracted medical records. The primary end points investigated by the CCSS included second cancers, mortality, and heart disease. Large registry-based cohort studies of childhood cancer survivors treated in Great Britain, France, the Netherlands, and the Nordic countries are ongoing and continue to contribute to our understanding of survivorship.[20,31-33] Within these cohort studies, the prevalence of and the risk factors for the development of late effects after childhood cancer have been better elucidated.

Interpreting Late Effects Research

Advances continue to be made in recognizing and categorizing adverse health outcomes in childhood cancer survivors. However, the study of late effects in cancer survivors has inherent challenges that must be considered when interpreting research findings. First, there is not universal implementation of a definition for "cancer survivor." The definition chosen for a particular investigation determines eligibility for studies and dictates how results can be interpreted and generalized to specific populations of survivors. The Office of Cancer Survivorship at the U.S. National Cancer Institute considers an individual a cancer survivor from the moment of cancer diagnosis through the balance of his or her life regardless of degree of cancer control.[34] Although this definition is meaningful, particularly from an advocacy perspective, it is not effective for the purposes of understanding late outcomes in a cured population. Survival 5 years beyond cancer diagnosis is the definition of cancer survivor that is often, but not universally, used for the purpose of research on late effects.

Another consideration is how investigators measure the late effect or outcome of interest. Self-report is frequently used to measure outcomes in epidemiologic studies of late effects. Although it is cost-effective, self-report can lead to reporting bias that results in inaccurate assessments of the incidence or severity of outcomes. Studies of smaller groups of survivors utilizing direct observation to delineate outcomes help to confirm self-reported outcomes, refine our understanding of these outcomes, and allow direct measurement of asymptomatic or early morbidity not evident by self-report. The disadvantages of this type of clinical studies are cost, complexity, and small sample size, which can limit interpretation of results.

The timing of assessments can also influence the results and interpretation of late effects research. Although it can be efficient to recruit survivors for follow-up studies during or soon after treatment, some late effects are not observed until decades after initial therapy. Studies with inadequate periods of follow-up might yield results that underestimate or overestimate late effects. Retaining survivors in observational cohorts over long periods of follow-up is challenging, and results may be biased toward retention of patients experiencing the outcomes under investigation. Consideration of the duration of follow-up is particularly important when applying results to populations of pediatric survivors, in whom late effects may emerge in the course of developmental change.

Another challenge when interpreting the results of late effect studies is that most results are reported as relative risks, the rate of an outcome observed in a cohort of survivors relative to the rate of the outcome observed in a control population. Elevated relative risks must be interpreted and communicated with caution, because even the smallest increase in an otherwise very rare outcome results in a very large relative risk; however, even a small or statistically insignificant increase in relative risk might have important clinical implications.

Comorbidities

Finally, an inherent difficulty with studying late effects is that treatments for cancer continue to evolve; therefore the health outcomes of interest in follow-up studies are often reflective of historic or outdated treatments. Methodology does not exist to address this issue, so treatment era must be taken into consideration when interpreting the results of these investigations. Duration of follow-up, treatment era, cohort eligibility, and outcome measures are all aspects of study design that merit careful consideration when interpreting results of late effects research studies.

General Principles of Late Effects

Epidemiologic studies investigating the association between treatment and risk for adverse health outcomes have led to general principles that contribute to our thinking about an individual survivor's potential for developing late effects (Box 72-1). A childhood cancer survivor's risk for developing late effects depends on the nature of prior treatment as well as individual characteristics, such as age at exposure, gender, or time since exposure.

First, the dose and intensity of the treatment is frequently correlated with risk for late effects. In general, survivors exposed to larger doses of therapy have worse outcomes. For example, risk for male infertility after treatment with gonadotoxic chemotherapy is directly related to dose; males exposed to the highest cumulative doses have the greatest risk for future infertility.[35] In addition, a survivor's likelihood for late effects is increased if there is exposure to more than one modality with related toxicities. For example, survivors treated concurrently with mediastinal radiation and cardiotoxic chemotherapy are at greater risk for cardiac late effects than those treated with either of those modalities alone.[36]

Organ toxicity associated with a single treatment exposure can manifest clinically as different late effects depending on the timing of the clinical assessment. For example, consider a postmenarchal female adolescent treated with gonadotoxic chemotherapy. During treatment she might experience acute reversible amenorrhea. Years later, after resolution of acute menorrhea, the woman might experience infertility secondary to premature menopause.

Over time, the same woman might have osteoporosis as a secondary late effect of chronic estrogen deficiency. Neurocognitive impairment after central nervous system (CNS) therapy provides another example of how the timing of assessment influences detection of late effects. Children treated with CNS therapy might not manifest treatment-related neurocognitive deficits until they reach a time when school work, employment responsibilities, or social interactions require more complex cognitive function. The clinical manifestations of a single treatment exposure can change over time and are influenced by the physical, emotional, and social needs of the individual survivor.

Duration of follow-up also influences the potential for late effects. Some irradiation-associated late effects, especially secondary malignancies, have long latency periods, with increases in cumulative incidence over time. In contrast, other treatment-related toxicities can be acute and resolve (bone marrow suppression) or occur late and be progressive (pulmonary fibrosis). The leukemogenic potentials of specific forms of chemotherapy appear to be associated with fairly discrete time frames after exposures: topoisomerase inhibiters are associated with occurrence of secondary leukemias within months of exposure and rarely beyond 5 years, whereas alkylating agents are associated with a later onset and a later, but still predictable plateau in cumulative incidence at 10 years after exposure.[37] In addition, acute chemotherapy organ toxicity can predict late toxicity. For example, chemotherapy-associated renal toxicity diagnosed during therapy can persist as a chronic condition or resolve and be diagnosed again as chronic renal disease decades after treatment. Although treatment exposures are the largest determinants of future late effects, a survivor's age or developmental stage during cancer treatment and his or her sex, family history, existing comorbidities, and health behaviors can all modulate risk for the development of late effects. In general, younger age at treatment is associated with a higher risk and/or greater severity for late effects. Children treated with cranial irradiation during the critical period of rapid brain development (<2 years old) are at greater risk for neurocognitive late effects than children treated when they are older.[38] In addition, female survivors are at greater risk than males for some late effects, including chemotherapy-associated cardiomyopathy, neurocognitive impairment, and second cancers, although the explanation for this gender difference is not clear.[39-42]

Underlying genetic predisposition for cancer (contributing etiologically to the primary cancer occurrence) will influence the risk for secondary cancers, as has been observed in hereditary retinoblastoma and nevoid basal cell carcinoma syndrome. In some patients, the only marker of this predisposition will be family history or a feature of the primary tumor itself (young age at occurrence, occurrence in paired organs). Predisposition to late effects based on genetic background is an area of great interest in survivorship research. Those survivors with a genetic predisposition to chronic medical conditions, such as heart disease, may be at greater risk for treatment-associated chronic conditions, such as radiation-associated coronary artery disease.[43] Recent genome-wide association studies have identified risk-specific polymorphisms that may become clinically relevant for predicting the risk for late effects and allow for potential tailoring of primary cancer therapy or follow-up. Most associations that have been described—for example, for ototoxicity after cisplatin exposure[44] or second cancer after irradiation[45]—await further validation. In addition, common medical comorbidities associated with aging, such as hypertension or hypercholesterolemia, may contribute to a survivor's risk for a variety of medical late effects, including chronic renal disease, heart disease, and cerebrovascular disease. Modifiable health behaviors such as diet, exercise, smoking, and sun exposure may also modulate a survivor's risk for late effects.

High rates of chronic health conditions have been described in adult survivors of childhood cancer.[46,47] In the CCSS cohort, the relative risk for a severe or life-threatening chronic condition in survivors when compared with siblings was 8.2 (95% confidence interval [CI], 6.9 to 9.7).[46] In the St. Jude Lifetime Cohort Study, the cumulative prevalence of a chronic condition was 95.5% (9%% CI, 94.8% to 98.6%) by age 45 years and 80.5% (95% CI, 73.0% to 86.6) for a severe or life-threatening or disabling condition.[47] The following section provides an overview of late effects experienced by survivors of childhood cancer. A summary of selected treatment-associated late effects is presented in Table 72-1.

SECOND CANCERS

Second cancers are the leading cause of treatment-related mortality in 5-year survivors. In the CCSS cohort, second cancers accounted for 13% of deaths overall and for 60% of deaths defined as treatment related.[17] Most often, a new cancer diagnosed in a survivor can be associated with a prior treatment exposure, such as radiation therapy or alkylating agent chemotherapy. Genetic cancer predisposition may also contribute to a survivor's risk for subsequent cancers. In addition, survivors, like all aging individuals, develop cancers that are not related to prior treatment or known genetic predisposition and these cancers will become more prevalent as the childhood cancer survivor population ages. To date, there are no data that address the comparative morbidity and mortality from these adult-onset cancers and whether survivors will be compromised in their ability to receive or respond to known effective therapies.

Overall, the likelihood of a childhood cancer survivor being diagnosed with a second primary cancer is three to six times greater than the risk in the aged-matched general population.[33,48-51] At 20 years after diagnosis, the cumulative incidence of second cancers in childhood cancer survivors is estimated at 3.2% to 4.2%.[48-50] In the British Survivorship Cohort, 5% of survivors had developed a secondary cancer by 38 years of age; this cumulative incidence of cancer would be expected at age 54 in a comparable, nonsurvivor population.[33] Clinical and demographic factors that increase the risk for second cancers include primary diagnosis, exposure to radiation, attained age, and chemotherapy with alkylating

TABLE 72-1 Selected Late Effects by Treatment Exposure

Treatment	Late Effect	Comments	Reference
Alkylating agents (busulfan, carmustine, lomustine, mechlorethamine, procarbazine, cyclophosphamide, ifosfamide, dacarbazine, melphalan)	Secondary leukemia/ myelodysplasia	Melphalan and mechlorethamine more leukemogenic than cyclophosphamide Median latency 4-6 years Dose-response relationship	23-25, 143-145
	Premature menopause	Risk factors: increasing cumulative total dose, concurrent pelvic radiation, increasing age, older age at treatment Myeloablative doses are associated with ovarian failure. Cryopreservation of oocytes or embryos are interventions to preserve fertility.	341, 343, 344
	Male infertility	Risk of azoospermia increases with increasing cumulative dose; spermatogenesis may recover over time. Highest dose is associated with impaired testosterone production. Pretreatment semen cryopreservation and testicular sperm extraction are interventions to preserve fertility.	35, 349, 351, 352
Anthracyclines (daunorubicin, doxorubicin, mitoxantrone, idarubicin)	Clinical heart failure	Risk factors: female gender, age <5 yr, cumulative doxorubicin equivalent dose >250-300 mg/m^2, concurrent radiation	152, 155, 156, 158, 175-177
Bleomycin, carmustine, busulfan (pulmonary toxic chemotherapies)	Pulmonary fibrosis	No plateau in incidence observed Radiation exposure an additional risk factor	215, 219
Platinum compounds (cisplatin, carboplatin)	High-frequency hearing loss	Cumulative dose cisplatin >450 mg/m^2 Risk factors: dose, age <5 yr Carboplatin ototoxic at myeloablative dose	326-329
	Speech frequency hearing loss	Cumulative dose cisplatin >720 mg/m^2 Rarely observed cumulative dose cisplatin <360 mg/m^2 Risk factors: dose, age <5 yr Carboplatin ototoxic at myeloablative dose	326-329
Topoisomerase II inhibitors (epipodophyllotoxins and anthracyclines)	Secondary leukemia	Median latency 1-3 yr Frequent administration increases risk (weekly/twice weekly).	24, 146-148, 149, 150
Any irradiation	Secondary sarcoma	Risk factors: increasing radiation dose, concurrent alkylating agent or anthracycline chemotherapy, young age at diagnosis, primary diagnosis of sarcoma or retinoblastoma, family history of sarcoma	66, 110-115
	Nonmelanomatous skin cancer	Fifty percent of survivors will have multiple lesions. Basal cell carcinoma—linear dose-response	118-120
	Melanoma	Risk factors: radiation dose >15 Gy, prior history melanoma, retinoblastoma, familial melanoma	115, 116
Cranial and head/neck irradiation (including TBI)	Growth hormone deficiency	High prevalence (85%-100%) with median dose 45-55 Gy Observed at 18-24 Gy, with lower prevalence and longer latency	223, 229-231
	Obesity	Risk factors: ≥20 Gy cranial radiation, female gender	282, 283, 285
	Hypothyroidism	Primary—direct neck radiation ≥10 Gy Central hypothyroidism—cranial dose >35 Gy Dose-response relationship with no plateau in incidence observed after neck radiation	93, 223, 226
	Thyroid cancer	Risk factors: radiation dose 15-30 Gy, young age at treatment, female gender	93-103
	Brain tumors	The most common pathologic processes are meningioma and glioma. Risk increases with increasing dose.	41, 122, 126
	Head and neck carcinoma	Parotid gland carcinoma most common; secondary head and neck carcinoma Risk of salivary gland carcinoma increases linearly with dose.	51,67,68, 138
	Stroke	Mean cranial radiation dose ≥30 Gy increased risk for both leukemia and brain tumor survivors. Highest risk after cranial dose ≥50 Gy	210, 212
	Dental abnormalities	Risk factors: age at diagnosis <5 yr, higher-dose radiation	416-419

TABLE 72-1 Selected Late Effects by Treatment Exposure (Continued)

Treatment	Late Effect	Comments	Reference
Chest irradiation (chest, mantle, lung, mediastinal, TBI)	Coronary artery disease	Increased risk with high-dose exposure	32, 36, 188, 192
	Cardiac valve disease	Increased risk with high-dose exposure	36, 43, 198
	Breast cancer	Risk factors: increasing radiation dose, age 10-30 years at diagnosis Latency: 10-15 years Ovarian failure reduces risk.	61, 82-85
	Lung fibrosis	Pulmonary—toxic chemotherapy an additional risk factor	216-219
	Lung cancer	Greatest risk in Hodgkin lymphoma survivors Increased risk in smokers	51, 65, 67, 85
	Thyroid cancer	Risk factors: radiation dose 15-30 Gy, young age at treatment, female gender	93-103
	Hypothyroidism	Risk factors: increasing radiation dose, older age at diagnosis, female gender No plateau in incidence observed over time	93, 223
Abdominal irradiation (abdominal, periaortic, flank)	Gastrointestinal cancer	Risk factors: dose >30 Gy; concurrent treatment with alkylating agents; increasing radiation dose and increasing radiation volume	72, 73,130
Pelvic irradiation (pelvic, inverted "Y," TBI)	Genitourinary cancer	Modestly increased risk overall; greatest risk for cancers of the female genital tract, bladder cancer, and renal cell carcinoma Risk factors: renal cell carcinoma renal irradiation, platinum-based chemotherapy, primary diagnosis of neuroblastoma	51, 67, 131
	Premature menopause	Risk factors: dose (≥1 to ≤20 Gy) and concurrent alkylating agent chemotherapy Pelvic radiation >10 Gy associated with ovarian failure Cryopreservation of oocytes or embryos is intervention to preserve fertility.	341-344
	Male hypogonadism	Risk of irreversible azoospermia >2 Gy Higher dose associated with impaired testosterone production, >20 Gy Pretreatment semen cryopreservation and testicular sperm extraction are interventions to preserve fertility.	264, 339, 349

TBI, Total-body irradiation.

agents or epipodophyllotoxins.[33] Diagnoses that confer the greatest risk for subsequent cancers include Hodgkin lymphoma (standardized incidence ratio [SIR], 8.7),[51] Ewing sarcoma (SIR, 8.5),[51] and retinoblastoma (relative rate [RR], 15).[49]

Genetic predisposition for second cancers results from an inherited or spontaneous germline mutation in a known or presumed cancer susceptibility gene. Characteristic findings in family cancer predisposition syndromes are younger age at cancer diagnosis, cancer in two or more generations, two or more cancers in an individual, and rare forms of cancer in combination.[52,53] An example of a rare cancer predisposition syndrome that is associated with pediatric malignancies is Li-Fraumeni syndrome, which is associated with germline mutations in the tumor suppressor gene *TP53*. It is inherited as an autosomal dominant trait and has a high penetrance with cancer risk of 50% by age 40 years.[52] The cancers most commonly observed in Li-Fraumeni syndrome are soft tissue sarcomas, breast cancer, leukemia, osteosarcoma, adrenocortical cancer, and brain tumors.

Survivors with an underlying genetic predisposition for cancer are more susceptible to treatment-associated secondary malignancies. This is demonstrated in survivors of retinoblastoma who carry a mutation in the *RB1* gene. Those with hereditary retinoblastoma treated with irradiation for their primary cancer have a cumulative risk for second cancers of 58% at 50 years, compared with 26% if not treated with irradiation.[54] There are other rare genetic syndromes that are associated with an increased susceptibility to pediatric cancers and subsequent adult-onset secondary cancers, and increasing evidence suggests that a substantial percentage of children with cancer may have an underlying cancer predisposition syndrome that might inform risk for subsequent cancers.[55] Genome-wide association studies of patients with and without secondary cancers may reveal polymorphisms associated with increased risk; for example, a study of Hodgkin lymphoma survivors who received irradiation identified two variants at genetic locus 6q21 that are associated with increased risk for a subsequent cancer.[45] Further work in this field may determine which survivors should undergo more intensive surveillance or prophylaxis for secondary cancer. All survivors of childhood cancer should be assessed for risk for secondary cancer based on a possible cancer predisposition, with attention to the family history as it evolves, development of benign disorders (e.g., polyps or hamartomatous lesions), as well as assessment of the pediatric history, including the primary diagnosis and age at diagnosis. Referral for genetic counseling for survivors of childhood cancer is increasingly important, because recent studies suggest that early genetic diagnosis and subsequent tumor surveillance may result in early diagnosis of secondary cancers in patients with known cancer predisposition syndromes (Box 72-2).[56,57]

Secondary Solid Tumors

Cancer that develops in a prior radiation field is the most common type of second cancer observed in survivors.[33,51] Risk estimates for second cancers have been reported from populations of survivors treated with irradiation during historic treatment eras when the modes of radiation therapy routinely used in clinical practice were different than current practices. In current oncology practice, orthovoltage radiation has been eliminated, thus reducing radiation doses to nontumor tissues such as skin, bones, and soft tissue. Large-dose extended-field radiation therapy is increasingly being replaced by involved-field lower-dose radiation therapy or conformal radiation therapy, often in combination with chemotherapy. It is assumed that this change in clinical practice aimed at reducing exposure to radiation will result in a lower incidence of radiogenic cancer; however, no “safe” dose of therapeutic radiation has been established and irradiation-associated cancers have been observed at what would be considered the lowest treatment doses.[58,59] In general, risk factors for irradiation-associated second cancers include treatment with radiation doses greater than 30 Gy, radiation in combination with alkylating agent chemotherapy, young age at exposure, more than 10 years beyond treatment, and the presence of a cancer predisposition syndrome.[25,27,60] Of particular concern is the observation that the cumulative incidence of irradiation-associated cancers does not plateau in groups of survivors followed for up to 50 years after their therapy for childhood cancer.[27,61-64] Second cancer risk is modulated by lifestyle choices; for example, adult survivors of Hodgkin lymphoma who smoke after exposure to chest irradiation have a 20-fold greater risk for secondary lung cancer compared with survivors who are nonsmokers.[65]

All tissues and organs are vulnerable to cancer induction by exposure to radiation. However, some tissues, such as thyroid and breast tissue, have greater sensitivity to radiation. Excluding low-grade nonmelanomatous skin cancer and (benign) meningiomas, the most frequently reported irradiation-associated second cancers in 5-year survivors of childhood cancer followed in the CCSS are, in order, breast cancer, thyroid cancer, CNS cancers, soft tissue sarcomas, and bone sarcomas.[48,66] Additional irradiation-associated second cancers reported in survivors, especially with longer follow-up intervals, include carcinomas of the head and neck (primarily parotid gland), colon cancer and other gastrointestinal cancers, lung cancer, and carcinomas of the genitourinary tract.[33,51,67,68-72,73] The most common second cancers observed in childhood cancer survivors are described next.

Breast Cancer

Breast cancer is one of the most frequently diagnosed irradiation-associated second cancers in childhood cancer survivors. Women treated with mantle, mediastinal, chest, spinal, whole-lung, and total-body irradiation during childhood or adolescents are at risk for secondary breast cancer.[27,61,62,68,74,75,76-81] Large cohort studies of childhood Hodgkin lymphoma survivors report a fifteen- to thirtyfold increased risk for irradiation-associated secondary breast cancer compared with the age-matched general population. Risk estimates vary by characteristics of the cohort, including radiation dose, age at therapy, and duration of follow-up. The cumulative incidence of secondary breast cancer is as high as 12% to 35% at 20 years after therapy for Hodgkin lymphoma, and the incidence does not plateau with longer duration of follow-up.[27,61,62,68,74-79]

Female survivors at greatest risk for secondary breast cancer are those treated between the age of 10 and 30 years with chest radiation doses greater than 20 Gy.[76,82] Studies have demonstrated a linear dose-response relationship between radiation dose and risk for secondary breast cancer.[76,83,84] The typical latency of irradiation-associated breast cancer is 10 to 15 years after therapy; however, secondary breast cancer has been reported in women as young as 20 years of age and as soon as 4 years after primary diagnosis.[61,85] Secondary breast cancer is most often associated with chest irradiation for Hodgkin lymphoma; however, it is important to recognize that women treated with chest irradiation for any childhood cancer diagnosis have increased risk for subsequent breast cancer, as illustrated in Figure 72-4.[61] Survivors of primary sarcomas not treated with chest irradiation also have an increased risk for secondary breast cancer (RR, 7).[61] Interestingly, survivors with therapy-induced ovarian dysfunction have a relative decreased risk for irradiation-associated breast cancers compared with survivors with normal ovarian function.[61,76,83] Although very rare, sporadic cases of male breast cancer have been reported in men treated with whole-lung irradiation as children.[10]

The most common type of breast cancer diagnosed in survivors is invasive ductal carcinoma; adverse biologic features (e.g., hormone-receptor negativity) may be more common in these childhood cancer survivors than in the general population.[61,74,86-88] Similar to findings in the general population, secondary breast cancer is detectable by radiographic imaging and has an excellent prognosis when treated in the earliest stages.[86] Breast cancer treatment options for survivors, however, can be limited by the therapy received for their childhood cancer. Specifically, prior anthracycline exposure and concern for potential cardiotoxicity may limit the use of adjuvant systemic chemotherapy with doxorubicin and the concern for tissue necrosis with repeated exposure to chest irradiation limits the option of breast-conserving surgery for some women.[86]

TABLE 72-2 Evaluation of Childhood Cancer Survivors for Irradiation-Associated Second Cancers

	Treatment Risk Factors	Clinical Evaluation	Special Considerations
Breast Cancer	Any chest irradiation Spinal irradiation TBI	Monthly breast self-examination Biannual clinical breast examination Breast MRI Mammogram	Current recommendations are to begin annual radiologic screening 8 years after irradiation or age 25 years, whichever occurs last.
CNS Tumor	Cranial irradiation Head /neck irradiation TBI	Annual neurologic examination Head MRI	Imaging studies are indicated for new or persistent neurologic symptoms.
Colorectal Cancer	Any abdominal irradiation Pelvic irradiation Spinal irradiation TBI	Colonoscopy Computed tomographic colonoscopy (CTC)	Current recommendations are to begin colonoscopy 10 years after radiation or age 35, whichever occurs last. CTC is not universally recommended as an alternative to colonoscopy in high-risk populations.
Thyroid Cancer	Neck irradiation Chest irradiation TBI MIBG	Annual clinical thyroid examination Thyroid ultrasound evaluation	Routine ultrasound screening is not currently recommended but should be considered for survivors with difficult clinical examination.
Skin Cancer	Any irradiation	Annual skin cancer screening Monthly skin self-examination	Practicing skin cancer prevention has potential to reduce risk.

TBI, Total-body irradiation.

Current screening recommendations for childhood cancer survivors treated with chest radiation published by the Children's Oncology Group include monthly self-breast examination, annual clinical breast examination, and annual breast magnetic resonance imaging (MRI) and mammography starting 8 years after treatment or age 25 whichever comes last.[89] Guidelines published by the American Cancer Society also advocate mammography and annual breast MRI, but suggest MRI only for women treated with chest irradiation between the ages of 10 and 30 years.[90] The addition of MRI to mammography has been reported to increase the sensitivity of breast cancer screening, although an impact on breast cancer outcomes has not been described (Table 72-2).[91]

Thyroid Cancer

Irradiation of the head and neck and upper thorax, total-body irradiation, and treatment with radioactive iodine (e.g., with ^{131}I-labeled-metaiodobenzylguanidine [MIBG])[92] place childhood cancer survivors at risk for subsequent thyroid cancers. Large cohort studies of childhood cancer survivors estimate relative risks for secondary thyroid cancer of between 4 and 36,[51,77,85,93-98] with a cumulative incidence of 1.3% at 30 years reported for female survivors and 4.4% in Hodgkin disease survivors.[85,99] Well-differentiated papillary carcinoma is the most common pathologic process (63% to 80%); however, follicular carcinomas are also observed.[68,85,96,97,100] The minimum observed latency period for secondary thyroid carcinoma is 5 years,[85,96,100] although cases have been reported closer to the time of original diagnosis.[85] At 20 years of follow-up, the relative risk for thyroid carcinoma remains increased[85,101] and a plateau in incidence has not been observed beyond 40 years of follow-up.[102] The risk for thyroid cancer is related to radiation dose; but unlike most other radiation-induced second cancers, the risk for thyroid cancer is greatest at lower doses of 15 to 30 Gy and beyond 30 Gy there is a decline in risk.[95,96,103] This finding demonstrates that thyroid tissue has enhanced sensitivity to radiation toxicity and supports the "cell kill" hypothesis that suggests higher doses of radiation cause cell death, which reduces the initiation of carcinogenesis observed at lower doses.[95] Although there is conflicting evidence, chemotherapy does appear to modify risk for irradiation-associated secondary thyroid cancer when the radiation dose is less than 20 Gy.[95,97,99,103] Female gender and young age at treatment are independent risk factors for secondary thyroid cancer.[85] Survivors of neuroblastoma treated with ^{131}I-MIBG are also at risk for subsequent thyroid cancer. In a single-institution case series of 16 neuroblastoma survivors treated with ^{131}I-MIBG and no external-beam irradiation, followed for a median of 15 years, 9 of 16 had nonpalpable thyroid nodules detected on thyroid ultrasonography, 6 of the 9 went on to biopsy, and 2 of those 6 were diagnosed with papillary thyroid carcinoma.[92]

Radiation-induced thyroid cancer in young survivors has an excellent prognosis; therefore many experts have recommended clinical screening. Appropriate screening schedules for secondary thyroid cancers and recommended modality for screening are controversial.[104-107] At a minimum, annual palpation of the thyroid for nodules by an experienced examiner is recommended.[89] Routine screening to detect subclinical thyroid nodules with high-resolution ultrasonography has been recommended by some investigators but remains controversial.[105,106] Ultrasound screening has the benefit of detecting smaller nonpalpable nodules but has the consequence of false-positive findings and potential for unnecessary biopsies.[106,107] Thyroid nodules do have ultrasound characteristics that are of concern for malignancy (hypoechogenicity, irregular margins, microcalcification). However, these findings are not diagnostic[108] and fine-needle aspiration of nodules larger than 1.0 cm or with suspicious features is usually necessary to evaluate for malignancy. Serial ultrasonography is then recommended to monitor thyroid nodules that are small or benign on biopsy.[108] Although clinical practice is moving toward using ultrasound to screen asymptomatic high-risk survivors for thyroid cancer, screening should be considered only after a discussion of the potential risks and benefits (see Table 72-2).

In general, irradiation-associated thyroid cancer is treated the same as other thyroid cancers and has an excellent prognosis. Thyroid surgery is indicated for nodules that are enlarging, are of indeterminate pathology on fine-needle aspiration, or are positive on fine-needle aspiration for malignancy.[108] Total thyroidectomy is often recommended to survivors because irradiation-associated thyroid cancers can be multicentric and because benign nodules can accompany clinically undetectable malignant lesions.[108] Finally, there is indirect evidence to support that exogenous thyroid hormone use reduces the risk for secondary thyroid cancer by suppressing thyroid stimulating hormone (TSH)-induced proliferation of thyroid nodules. Although not proven to reduce risk for thyroid cancer, the use of exogenous thyroid hormone to suppress thyroid proliferation is supported by data that show a decrease in incidence of new thyroid nodules in patients treated with exogenous thyroid hormone after partial thyroidectomy (34% vs. 14%).[109]

Sarcomas

Survivors treated with radiation are at increased risk for secondary cancer of the bone and soft tissue in the radiation field. Although secondary sarcomas are most often associated with irradiation, survivors of primary sarcoma and hereditary retinoblastoma who have not had prior radiation therapy also have an increased risk, suggesting a genetic predisposition.[54,110,111] Risk estimates for secondary sarcoma vary by type of sarcoma and composition of the study cohort.[60,63,110,112,113] The CCSS cohort, which did not include survivors of retinoblastoma, reports an overall ninefold increased risk for secondary sarcomas and an absolute excess risk of 32.5 per 100,000 person-years.[110] Secondary sarcomas occurring after childhood cancer include multiple histologic subtypes such as osteosarcoma, nonrhabdomyosarcoma soft tissue sarcomas, primitive neuroectodermal tumors (Ewing sarcoma), and malignant peripheral nerve sheath tumors, as well as rarer sarcoma subtypes.[110] The median latency for secondary sarcomas is 11 years, with increased risk persisting beyond 20 years.[63,110] Reported risk factors for subsequent sarcomas include higher doses of radiation, primary diagnosis of sarcoma or hereditary retinoblastoma, younger age at diagnosis, alkylating agent exposure, anthracycline exposure, and family history of sarcoma.[63,110,112-114] A nested case-control study of secondary sarcomas in the CCSS cohort identified a dose-response relationship between radiation dose and risk for secondary sarcomas, with elevations in risk ratios with higher radiation doses: 10 to 29.9 Gy (odds ratio [OR], 15.6; 95% CI, 4.5 to 53.9), 30 to 49.9 Gy (OR, 16.0; 95% CI, 3.8 to 67.8), and more than 50 Gy (OR, 114.1; 95% CI, 13.5 to 964.8).[66] Risk factors other than irradiation associated with increases in risk for secondary sarcoma in this study included primary cancer diagnosis of sarcoma or Hodgkin lymphoma and anthracycline exposure.[66]

For survivors of hereditary retinoblastoma treated with irradiation, the risk for subsequent bone sarcomas is as high as 400-fold with a cumulative incidence at 20 years of 14.1% and the relative risk for soft tissue sarcomas is 140 with 50-year cumulative incidence of 13%.[60,63,111] Radiation exposure and underlying genetic predisposition both contribute to risk for secondary sarcomas in retinoblastoma survivors.[60,63,111]

Routine radiographic screening for secondary sarcomas is currently not recommended. Survivors at risk for secondary sarcomas should be counseled to report new pain, lesions, or masses in the radiation field and should be promptly evaluated for any signs or symptoms suggestive of a secondary sarcoma. As survivors enter follow-up care, providers should consider obtaining baseline imaging of any previously irradiated site, so these studies are then available for comparison should symptoms suggestive of a new malignancy develop. There is no established role for secondary sarcoma surveillance for survivors of hereditary sarcoma predisposition syndromes (Li-Fraumeni syndrome, hereditary retinoblastoma), although the role of whole-body MRI is currently under investigation.

Skin Cancer

Melanoma and nonmelanomatous skin cancers are reported with increased incidence in survivors. The relative risk for melanoma is 2.5 to 9.0 in childhood cancer survivors, with a median latency of 15 to 18 years.[48,51,115,116] Survivors of hereditary retinoblastoma, familial melanoma syndromes, and those with a prior history of melanoma all have an increased risk for subsequent melanoma independent of irradiation.[49,55,111,117] Although the association between therapeutic radiation and melanoma is not firmly established,[116] a case-control study of 16 survivors with secondary melanoma in a European cohort of 4000 childhood cancer survivors found an association between secondary melanoma and exposure to more than 15 Gy of radiation.[115] In contrast, basal cell carcinomas and squamous cell carcinomas are known to be more common in radiation-exposed survivors (RR, 6.3), with 90% of all nonmelanomatous skin cancers diagnosed in previously irradiated fields.[118,119] A linear dose-response relationship is described for basal cell carcinomas, with an excess odds ratio of 1.09 per Gy of radiation.[120] Also of note, these low-grade skin cancers can be recurrent, and almost half of survivors diagnosed will have multiple lesions.[119] The prognosis for secondary skin cancers is excellent with early diagnosis; therefore routine screening

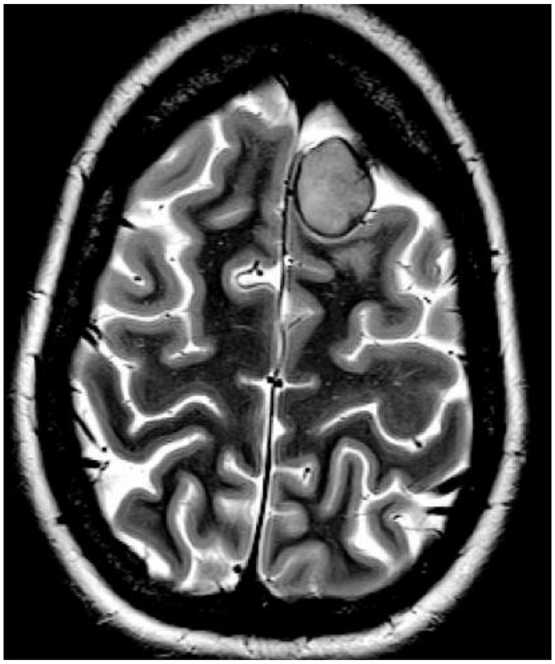

Figure 72-5 MR image of meningioma in a 20-year-old with a history of relapsed acute lymphoblastic leukemia, with therapy including total-body irradiation, presenting with headache. Note frontal mass. Pathology was consistent with meningioma.

with skin examinations is recommended.[121] Because ultraviolet radiation from the sun is known to contribute to skin cancer risk; patients should be routinely educated about preventive strategies such as aggressive sun exposure protection (see Table 72-2).

Central Nervous System Tumors

Past exposure to cranial irradiation is considered the most important risk factor for the development of subsequent CNS tumors in survivors of childhood cancer.[41,122] The most common pathologic processes include meningioma (Fig. 72-5) and glioma; however, other tumors such as primitive neuroectodermal tumor or medulloblastoma have been reported.[41,49,123-125] In a report from the British Childhood Cancer Survivor Study, the standardized incidence ratio for development of a subsequent glioma was 10.8 (95% CI, 8.5 to 13.6),[126] and in the CCSS cohort it was 8.7 (95% CI, 6.2 to 11.6).[41] Higher standardized incidence ratios have been reported for meningioma,[122] and meningioma is the most common subsequent CNS tumor 10 years or more after a childhood cancer diagnosis.[41,124] There is an established dose-response relationship between cranial radiation dose and incidence of secondary CNS tumors. In the CCSS cohort, Neglia and colleagues reported an excess relative risk of 1.06 per Gy of cranial irradiation for meningiomas and 0.3 per Gy for gliomas.[41] In the British Childhood Cancer Survivor Study cohort, Taylor and colleagues reported that the risk for glioma and for meningioma each increased linearly with increasing radiation dose.[126] Several studies have suggested that the increased risk for development of meningioma does not appear to plateau.[118,123,127] In a report from the CCSS, among survivors with no previous diagnosis of meningioma at 25 years after a primary CNS tumor, the cumulative incidence of meningioma at 30 years was 3.5% (95% CI, 0.9% to 6.1%).[123] The contribution of chemotherapy to the risk for CNS malignancies is controversial. Laboratory investigations have suggested an association between radiation-induced brain tumors and thiopurine-based chemotherapy related to a deficiency in the enzyme thiopurine methyltransferase (TPMT).[128] In the British Childhood Cancer Survivor Study cohort, a higher cumulative dose of intrathecal methotrexate was associated with the development of meningioma.[126] In the CCSS cohort, after adjusting for radiation dose, chemotherapy exposure did not alter the survivor's secondary brain tumor risk.[41]

The role of routine surveillance for secondary CNS tumors with neuroimaging in asymptomatic childhood cancer survivors requires further investigation. Single-institution series of neuroimaging screening have reported high rates of meningioma.[127,129] For example, in a prospective study of 76 survivors of acute lymphoblastic leukemia that was treated with cranial irradiation and who were screened with MRI every 3 to 6 years for 20 years, Goshen and colleagues detected 16 meningiomas (15 asymptomatic) and one glioma.[127] Cumulative incidence in this screened population was 14.8% at 20 years.[127] Surgical resection of these secondary CNS tumors was recommended for 12 of the 16 survivors, with one surgical complication reported.[127] Whether early detection of meningiomas in asymptomatic survivors might reduce morbidity and minimize neurologic complications by facilitating surgical intervention remains to be determined. Survivors with a prior history of cranial irradiation should be educated about the potential for late-occurring CNS tumors and instructed to report new or persistent neurologic signs or symptoms (see Table 72-2).

Other Cancers

Secondary carcinomas of the gastrointestinal tract, genitourinary organs, lung, and head and neck region are observed in survivors of childhood cancer and are associated with radiation exposure and longer follow-up times. In general, irradiation-associated carcinomas (like colon cancers) occur at an earlier age than is seen in the general population, thereby supporting recommendations for early initiation of cancer screening and aggressive evaluation of symptoms suggestive of possible secondary malignancy.

Large cohorts of childhood cancer survivors report relative risks for gastrointestinal cancers between 4.6 and 7.0.[33,49,67,68,72,73] A European cooperative cohort study found the risk for secondary gastrointestinal malignancies greatest after abdominal radiation dose greater than 30 Gy (SIR, 9.7); however, lower-dose radiation was also associated with increased risk (10 to 29 Gy, SIR 5.2).[72] Alkylating agent chemotherapy is consistently found to be independently associated with an increased risk for gastrointestinal cancer.[72,73,130] The most common irradiation-associated secondary gastrointestinal malignancy is colorectal cancer, with a standardized incidence ratio of 3.6 to 13 and as high as 63.4 (95%

CI, 15.7 to 71.8) reported in a cohort of Hodgkin lymphoma survivors.[68,72,73,130] In a British cohort of 18,000 childhood cancer survivors, the 50-year cumulative incidence of colorectal cancer for those treated with direct abdominal radiation was 1.4% (95% CI, 0.7 to 2.6).[33] The St. Jude Children's Research Hospital cohort of over 13,000 childhood cancer survivors found a 40-year cumulative incidence of secondary colorectal cancer of 1.4% ± 0.53%).[130] In this study, the risk for colorectal cancer increased by 70% with each 10-Gy increase in radiation dose and increasing radiation volume also significantly increased risk. Current recommendations for screening of survivors treated with abdominal radiation therapy are to begin colon cancer screening earlier than what is recommended for the general population (10 years after completing radiation therapy or age 35 years, whichever comes last), although the benefit of early surveillance has not be established in this high-risk population (see Table 72-2).[89]

Of note, gastric cancers and esophageal cancers are also observed in greater numbers than expected for age in survivors of pediatric Hodgkin lymphoma.[68,85] Common symptoms such as dysphagia and dyspepsia should be evaluated aggressively, with a low threshold for utilizing endoscopy or imaging to rule out malignant or premalignant conditions in exposed survivors.

Overall, the relative risk for genitourinary cancer is modestly elevated (SIR, 1.9; 95% CI, 1.6 to 2.4),[33] with elevated relative risks for secondary malignancies of the female genital tract (SIR, 2.1; 95% CI, 1.4 to 3.2),[51] secondary renal cell carcinoma (SIR, 8.0; 95% CI, 5.2 to 11.7),[131] and secondary bladder cancer (SIR, 5.1; 95% CI, 2.1 to 12.4).[67] Data from the CCSS show the risks for secondary renal carcinoma are primary diagnosis of neuroblastoma (SIR, 85.8; 95% CI, 38.4% to 175.2%), renal-directed radiation therapy of 5 Gy or greater (RR, 3.8; 95% CI, 1.6 to 9.3), and platinum-based chemotherapy (RR, 3.5; 95% CI, 1.0 to 11.2).[131] Secondary urinary bladder cancer is associated with both radiation therapy and cyclophosphamide chemotherapy, with the risk dependent on dose and duration of therapy.[67,132-135] An adult series of more than 6000 non-Hodgkin lymphoma survivors treated with cyclophosphamide reported 31 cases of bladder cancer (RR, 4), and no significantly increased risk was observed at doses less than 20 g/m^2.[133] In a British cohort of 18,000 childhood cancer survivors, 17 were diagnosed with bladder cancer (RR, 4); risk factors were diagnosis of hereditary retinoblastoma, treatment with chemotherapy, male gender, and longer follow-up.[135] In another series of adults treated with prolonged cyclophosphamide for nonmalignant disease, 5% developed secondary bladder cancer at a median of 8.5 years and all diagnoses were preceded by symptoms of microscopic hematuria.[136] Although the absolute excess risk for bladder cancer in childhood cancer survivors is low, routine monitoring with urinalysis of survivors exposed to pelvic radiation, large cumulative dose of cyclophosphamide, and those with hereditary retinoblastoma should be considered.

Cancer of lung and bronchus is diagnosed more commonly in childhood cancer survivors than the general population (SIR, 3.4; 95% CI, 1.9 to 6.1),[51] with greater risk observed in cohorts of pediatric Hodgkin lymphoma survivors (SIR, 5.1 to 27.2).[67,85] In a meta-analysis of secondary lung cancer in Hodgkin lymphoma survivors, the largest risk for secondary lung cancer was observed among patients diagnosed age 15 to 24 years (RR, 8.76; 95% CI, 4.55 to 16.89).[137] Treatment with alkylating agents and irradiation are both associated with increased lung cancer risk.[67] In addition, studies of adult survivors of Hodgkin lymphoma have shown that smoking increased lung cancer risk more than twentyfold. Aggressive smoking cessation interventions and routine surveillance with radiographic imaging have been suggested for this high-risk population of survivors, although the use of spiral computed tomography has not been studied in the survivors who had chest irradiation.

Survivors are also at increased risk for secondary head and neck carcinomas (SIR, 10.8 to 14.1), with mucoepidermoid carcinoma of the parotid gland the most frequently observed diagnosis.[51,67,68] In a CCSS analysis of secondary salivary gland carcinomas, the incidence was thirty-ninefold higher in survivors compared with the general population (95% CI, 25.4 to 57.8).[138] The analysis also demonstrated that risk increased linearly with radiation dose (excess RR, 0.36/Gy; 95% CI, 0.06 to 2.5).[138] Interestingly, modifiable health behaviors including cigarette smoking and alcohol intake were not associated with increased risk for head and neck cancers in childhood cancer survivors.[138]

Hematologic Malignancies

Childhood cancer survivors are at an increased risk for developing subsequent hematologic malignancies, particularly secondary acute myelogenous leukemia. Overall, the relative risk for secondary acute leukemia in childhood cancer survivors is reported from 7 to 20.[23,24,48,49,68,77,139,140] An increased risk for secondary leukemia is described after treatment of a primary solid tumor[139] and after treatment of acute lymphoblastic leukemia, particularly with exposure to a topoisomerase II inhibitor.[141] In an analysis of survivors of cancer diagnosed when younger than 20 years of age, utilizing the Surveillance, Epidemiology, and End Results (SEER)-9 database, the cumulative incidence of secondary hematologic malignancy at 5 years was 0.2% (± 0.03%) and at 10 years it was 0.4% (± 0.04).[142] In contrast to irradiation-associated malignancies, the latency for leukemogenesis associated with chemotherapy is within the first 10 years after treatment, with the greatest risk observed in the first 5 years off therapy. In a study of 4202 survivors of childhood solid tumors, the relative risk of leukemia was 20 at 3 to 5 years and then decreased to 2.2 by 10 years off therapy.[139] Of interest, in this same study a second peak in secondary leukemia was observed at 20 years or more of follow-up (RR, 14.8); this finding has not been observed in studies with shorter follow-up periods.[24,48,62]

Acute leukemias and myelodysplasia are associated with exposure to high cumulative doses of alkylating agents and topoisomerase II inhibitors, including epipodophyllotoxins and anthracyclines. The alkylating agents presenting the greatest concern for secondary leukemia risk are melphalan and mechlorethamine, when compared with cyclophosphamide and ifosfamide.[23,25,143] Secondary leukemias induced by exposure to high-dose alkylating agents are classically considered to be preceded by myelodysplasia, have a median latency of 4 to 6 years, are more often diagnosed in older children, and are often associated with losses or deletions of chromosome 5 or 7.[37] Higher cumulative dose of alkylating agents is associated with a greater risk for the development of secondary acute myelogenous leukemia.[144] Interestingly, more recent pediatric studies demonstrated lower overall rates of leukemia after alkylating agent exposure[139,145] than earlier studies,[23,24] likely reflecting the trend of treatment with lower cumulative doses of less leukemogenic alkylating agents in more modern cohorts.

Topoisomerase II–induced leukemias, on the other hand, typically do not have an indolent course, have a relatively short latency (median, 1 to 3 years), are diagnosed in younger children, and are associated with a balanced chromosomal translocation 11q23 and, less frequently, 21q22.[24,37,146,147] Some have reported an increased risk for secondary acute myelogenous leukemia with higher cumulative epipodophyllotoxin dose. For example, in a case-control study of 61 cases of secondary leukemia in childhood survivors, Le Deley and colleagues reported a greater than twentyfold increased risk for leukemia after exposure to greater than 6 g/m^2 of epipodophyllotoxins and a sevenfold increased risk after exposure to either 1.2 to 6 g/m^2 epipodophyllotoxins or greater than 170 mg/m^2 of anthracyclines compared with lower doses of these agents.[145] However, other investigators have not demonstrated a relationship between higher cumulative epipodophyllotoxin dose and the development of secondary acute myelogenous leukemia.[148,149] Schedule of administration of epipodophyllotoxins may contribute to the risk for secondary leukemia, because prolonged infusions (twice weekly, weekly) have been found to be an independent risk factor for development of leukemia.[148,150]

The contributory role of therapeutic doses of radiation in the development of secondary leukemia is debated. Although some studies find no association between leukemia and exposure to radiation therapy,[49,139,148] others studies have documented subsequent leukemia in survivors after exposure to radiation in the absence of chemotherapy.[24,37,139] In addition, specific host factors, such as polymorphisms of DNA repair genes, may contribute to susceptibility to secondary acute myelogenous leukemia.[144]

The prognosis of secondary acute myelogenous leukemia is generally considered to be poor.[37,146] In the SEER-9 analysis cited earlier, the 5-year overall survival for patients with secondary hematologic malignancies was 31% ± 4.7%.[142] In a report of 24 children with secondary myelodysplastic syndrome or acute myelogenous leukemia, those with secondary myelodysplastic syndrome or acute myelogenous leukemia had lower rates of remission with induction therapy and poorer overall and event-free survival when compared with patients with de novo acute myelogenous leukemia.[151] Further investigation is needed to determine the optimum strategies for preventing and treating secondary leukemia.

ORGAN SYSTEM LATE EFFECTS

Cardiovascular System

Cardiac disease is the leading cause of treatment-related morbidity and noncancer mortality observed in childhood cancer survivors.[152] In an analysis of late mortality among 5-year survivors of childhood cancer from the CCSS cohort, childhood cancer survivors were seven times more likely to die of cardiac-related events compared with expected population-based rates of cardiac-related deaths.[21] Indeed, childhood cancer survivors have been reported to be at significantly increased risk, compared with a sibling cohort, for the development of congestive heart failure (RR, 15.1; 95% CI, 4.8 to 47.9,), coronary artery disease (RR, 10.4; 95% CI, 4.1 to 25.9), and cerebrovascular accidents (RR, 9.3; 95% CI, 4.1 to 21.2).[46] The treatments most often associated with cardiac morbidity and mortality are anthracycline chemotherapy and cardiac irradiation.[21] A recent cohort study assessing the long-term risk for clinically validated, symptomatic cardiac events in 5-year survivors of childhood cancer demonstrated that higher cumulative anthracycline dose or higher cumulative radiation dose was associated with higher risk ratio for cardiac events. Survivors with both anthracycline and cardiac irradiation exposures had the highest cumulative incidence of cardiac events, with nearly one in eight survivors treated with both exposures developing a serious cardiac event.[36] Risk factors for late onset anthracycline cardiotoxicity (occurring 1 year beyond completion of therapy) have been assessed in multiple studies and include higher cumulative anthracycline dose, history of acute cardiac toxicity, combined exposure with other cardiotoxic therapy, female sex, younger age at exposure (<5 years old), and longer duration of follow-up.[42,153-158] Irradiation of the heart as a consequence of irradiation to the chest for treatment of childhood cancer can cause both functional and anatomic cardiac disease. Mantle field, whole-lung fields, left- or whole-abdominal irradiation, spinal irradiation, and total-body irradiation all put a survivor at risk for cardiac late effects.[155,159-162] Irradiation-associated cardiac late effects include constrictive pericarditis,[163] myocardial fibrosis,[164] cardiomyopathy, coronary artery disease, valvular abnormalities, conduction disturbances, and vascular disease.[43,155,159] Similar to other irradiation-associated late effects, cardiac toxicity is observed more frequently in those survivors treated at the youngest age, receiving higher radiation dose volumes to the heart, and followed the longest.[159,160]

Nonanthracycline chemotherapeutic agents, including cyclophosphamide, cytarabine, cisplatin, and ifosfamide, have also been associated with cardiotoxicity.[152] In addition, children and adolescents are increasingly being treated with newer agents with unclear cardiac risks. For example, tyrosine kinase inhibitors (imatinib mesylate, sorafenib, and sunitinib) have been associated with cardiac toxicity with exposure in adulthood.[165,166] Cardiac risks with prolonged exposures to newer agents in large cohorts of pediatric patients are yet to be defined.

The spectrum and nature of cardiac late effects experienced by childhood cancer survivors suggest a need for regular screening with one or more cardiac imaging modalities. Risk-based screening recommendations for childhood cancer survivors exposed to cardiotoxic therapies have been published by the Children's Oncology Group as part of the "Late Effect Guidelines" as well as by other groups.[89,167,168] However, these guidelines have not been tested for efficacy in terms of reduction of cardiac mortality or morbidity. Survivors exposed to cardiotoxic therapy should be informed about their risk for cardiac disease and should also be made aware of activities that present potential stressors to already impaired cardiac function, including smoking, pregnancy, and anesthesia.

Cardiomyopathy

Cardiomyopathies diagnosed in childhood cancer survivors after completion of therapy are associated with both anthracycline chemotherapy and cardiac irradiation. Survivors are at risk for both systolic and diastolic left ventricular dysfunction, which can lead to clinical heart failure.[169-171] Anthracycline-associated cardiotoxicity can be classified as acute, early onset (<1 year after anthracycline exposure), or late onset (>1 year after anthracycline exposure),[158] although it is not clear to what extent these categories reflect differences in underlying pathophysiology.[172] Anthracyclines are considered to be directly toxic to cardiac myocytes, with exposure resulting in reduced myocyte mass and impaired function of cardiac muscle. Subclinical anthracycline cardiotoxicity is measured as diminished left ventricular contractility and a thinning of the left ventricular wall. Thinning of ventricular walls causes elevated wall stress, which increases afterload, and ultimately can progress to symptomatic left ventricular failure. In children, loss of cardiac myocytes at a young age can result in impaired cardiac growth and function relative to somatic growth, which contributes to the observed decrease in left ventricular systolic function.[42,173] Anthracycline-associated late cardiac toxicity can manifest as asymptomatic cardiac dysfunction detected by echocardiogram or other modalities or symptomatic dysfunction and the classic signs of heart failure.[155,156] Longitudinal and long-term follow-up data support that cardiac abnormalities diagnosed in childhood cancer survivors treated with anthracyclines are persistent and progressive.[174,175] In a Dutch cohort of more than 800 anthracycline-exposed childhood survivors, the cumulative incidence of anthracycline-induced clinical heart failure increased with the duration of follow-up; there was a cumulative incidence of 2.6% at 10 years and 5.5% at 20 years, with no evidence of plateau in incidence with longer duration of follow-up.[157] Of further concern, the incidence of asymptomatic left ventricular dysfunction detected by cardiac screening is reported to be as high as 50% to 60%.[153,176] However, the long-term clinical implications of subtle echocardiographic abnormalities in asymptomatic individuals are not fully determined.

Many risk factors for anthracycline-associated cardiomyopathy have been identified. The major risk factor for anthracycline cardiomyopathy is cumulative dose ("doxorubicin equivalent"). Equivalent dose takes into consideration exposure to different anthracyclines and can be calculated using conversion factors (Table 72-3). Survivors exposed to cumulative doses of doxorubicin equivalents greater than 250 to 300 mg/m^2 appear to be at greatest risk for cardiomyopathy.[19,42,157,175,177,178] The dose-dependent relationship between anthracyclines and subsequent congestive heart failure was demonstrated in the Dutch cohort, where the greatest risk for congestive heart failure was at a dose greater than 300 mg/m^2 (RR, 8), and no congestive heart failure was observed at doses less than 150 mg/m^2.[157] However, others have shown that survivors treated with low cumulative dose (45 mg/m^2) also have asymptomatic cardiac abnormalities detectable on an echocardiogram,[174] suggesting that exposure to anthracycline at any dose poses potential risk for late cardiotoxicity.

TABLE 72-3 Calculation of Anthracycline (Doxorubicin) Isotoxic Dose Equivalents*

Anthracycline	Conversion Factor
Doxorubicin	Total dose (mg/m^2) × 1
Daunorubicin	Total dose (mg/m^2) × 1
Mitoxantrone	Total dose (mg/m^2) × 4
Idarubicin	Total dose (mg/m^2) × 5
Epirubicin	Total dose (mg/m^2) × 0.67

From the Children's Oncology Group long-term follow-up guidelines for survivors of childhood, adolescent, and young adult cancers, *Version 4.0. Accessed at www.survivorshipguidelines.org, October 2013.*

*Estimation of anthracycline isotoxic dose equivalents for use in calculation of total cumulative anthracycline dose.

Additional reported risk factors for the development of anthracycline-associated cardiomyopathy include history of acute cardiac toxicity during treatment, combined exposure with other cardiotoxic therapy, female sex, younger age at exposure (<5 years of age), and longer duration of follow-up.[42,153-157] Cardiotoxicity diagnosed during or within 1 year of completion of therapy is considered a risk factor for late cardiotoxicity.[152] Furthermore, survivors exposed to anthracycline therapy and concurrent mediastinal radiation are considered to be at risk for cardiomyopathy at lower total anthracycline dose.[160] Increasingly, genetic variants that may predispose to anthracycline cardiotoxicity are being explored.[177,179] A recent evaluation from the Children's Oncology Group demonstrated that patients with *CBR3* V244M homozygous G genotype with low- to moderate-dose anthracycline exposure were at an increased risk for cardiomyopathy.[177]

Interventions aimed at preventing or reducing long-term anthracycline-associated cardiotoxicity in childhood cancer survivors include limiting anthracycline doses in most therapeutic regimens to less than 300 mg/m^2, adding cardioprotectants such as dexrazoxane to anthracycline-based regimens, and prescribing afterload-reducing agents to prevent progression of asymptomatic dysfunction to overt heart failure. Data from clinical trials in childhood ALL show that the addition of cardioprotectants did not adversely affect survival.[180] Although an early analysis of a Pediatric Oncology Group clinical trial for Hodgkin lymphoma, which randomized the use of dexrazoxane as a cardioprotectant, demonstrated a possible increase in second cancers with dexrazoxane exposure,[181] a larger cohort of survivors of childhood acute lymphoblastic leukemia treated with dexrazoxane did not demonstrate an increased risk for second cancers.[182] Childhood cancer survivors diagnosed with anthracycline-associated left ventricular dysfunction have been treated with angiotension-converting enzyme inhibitors with the aim of reducing afterload and preventing the progression of left ventricular dysfunction to heart failure. In a longitudinal study of 18 survivors with left ventricular dysfunction, treated with enalapril and followed for a median of 10 years, all initially showed improvement in left ventricular function. The effects, however, were transient, lasting 6 to 10 years, followed by deterioration of left ventricular function over time.[183] However, given results from large studies of medical interventions for patients with asymptomatic left ventricular dysfunction (who have not received anthracyclines), as well as data from adult cancer patients,[184,185] many cardiologists who evaluate and treat adults with anthracycline-induced cardiomyopathy will intervene with angiotensin-converting enzyme inhibitors. Future investigations should be directed at testing interventions to prevent cardiac injury during therapy and to prevent progression of asymptomatic left ventricular dysfunction to overt cardiac disease in survivors.

Irradiation-associated cardiomyopathy is most often restrictive, with impaired diastolic function, although systolic dysfunction may also be observed.[163,164] Radiation is believed to induce injury to the myocardial microvasculature, which in turn causes myocardial ischemia, and ultimately myocardial fibrosis, resulting in diastolic dysfunction.[37] Studies have demonstrated a significant incidence of diastolic dysfunction in asymptomatic patients who undergo radiation therapy.[159,186,187] In a small cohort of Hodgkin lymphoma survivors treated with a median mediastinal dose of 35 Gy, evaluated at a mean of 9 years after therapy, 20% had evidence of diastolic dysfunction on cardiac imaging.[186] The extent to which these changes are progressive, and whether subclinical dysfunction will result in clinical heart failure over time, is unknown. As noted earlier, there is a significantly increased risk for cardiotoxicity with combined exposure to both anthracyclines and irradiation.[36,159,188]

Screening for cardiomyopathy with serial echocardiograms is currently recommended for survivors treated with anthracyclines and/or thoracic radiation therapy, with the frequency of echocardiogram screening depending on the individual survivor's risk for cardiomyopathy as determined by age at exposure, cumulative treatment dose, and concurrent treatment with thoracic irradiation.[89] The use of newer modalities for screening, such as cardiac MRI, is an area of active investigation.[189] The extent to which screening will result in a reduction in cardiac morbidity and mortality in survivors remains unknown.

Coronary Artery Disease

Survivors treated with thoracic irradiation are at increased risk for the development of radiation-associated coronary artery disease (CAD), which is an established cause of early mortality.[109,190] Radiation injury to the coronary arteries is considered to be caused by acute endothelial damage followed by subsequent initiation or acceleration of atherosclerosis.[152,160] Irradiation-associated coronary artery stenosis is most common in the proximal coronary arteries, which are not necessarily shielded during cardiac blocking.[191] In a historic cohort, childhood Hodgkin lymphoma survivors treated with more than 40 Gy of mediastinal radiation had a fortyfold excess risk for fatal myocardial infarction compared with an age-matched general population.[192] A report on 314 Hodgkin lymphoma survivors treated at age younger than 20 years found a fivefold increased risk for myocardial infarction at a median of 19 years after treatment,[188] and a British cohort that included 2158 Hodgkin lymphoma survivors treated at age younger than 25 years found a nineteenfold increased risk for death from myocardial infarction.[32] A recent study assessing the long-term risk for clinically validated, symptomatic cardiac events in 5-year survivors of childhood cancer demonstrated a significantly increased 30-year cause-specific cumulative incidence of cardiac ischemia for survivors treated with cardiac irradiation compared with survivors treated without cardiac irradiation (2.2% [95% CI, 0% to 4.7%] vs. 0.3% [95% CI, 0% to 0.8%], $P = .01$)].[36] Modern irradiation techniques are designed to reduce radiation to the coronary arteries, although reduction in irradiation-associated CAD has not yet been proven.

The risk for asymptomatic CAD in survivors is described in many studies; however, optimal screening and interventions to detect and treat irradiation-associated cardiovascular disease have not been determined. Survivors at risk for irradiation-associated CAD are advised to adopt preventive measures commonly used to reduce the risk for atherosclerotic CAD in the general population (aggressive treatment of hypertension, diabetes, obesity, dyslipidemias). Although the efficacy of such measures is not proven in this population, at least one cardiac risk factor was present in all survivors who developed CAD in a single-institution study of 415 Hodgkin lymphoma survivors[43]; these data suggest that standard cardiovascular risk–reducing strategies might be beneficial to survivors.

Stress echocardiograms can be used as a noninvasive method to detect asymptomatic ischemic heart disease by observing stress-induced wall motion abnormalities. Noninvasive nuclear scintigraphy has also been considered to screen survivors for asymptomatic CAD. A report of screening 294 asymptomatic Hodgkin lymphoma survivors treated at a median age of 25 years with more than 35 Gy found 20% had electrocardiographic findings consistent with prior ischemia and 14% had abnormal stress echocardiograms or stress-induced perfusion defects by nuclear scintography.[193] The survivors with abnormal nuclear perfusion studies who went on to cardiac catheterization were diagnosed with irradiation-induced microvascular damage in the myocardium that was not amendable to surgical intervention.[193] This study showed that the increased sensitivity of adding perfusion scanning in addition to stress echocardiography was at the expense of decreased specificity, with false-positive detection of disease not amendable to intervention. This calls into question the benefit of adding nuclear studies to routine screening of asymptomatic survivors for CAD. The roles of modalities such as CT angiography, MR angiography, and coronary artery calcium scores in the childhood cancer survivor population are yet to be established.[152,194]

Surgical treatment of CAD in survivors with prior radiation exposure can be complicated by mediastinal fibrosis, myocardial fibrosis, and the coexistence of other irradiation-associated morbidities, including valvular disease, conduction abnormalities, and pulmonary dysfunction.[195] In a recent report from Wu and colleagues, adults with irradiation-associated heart disease undergoing cardiothoracic surgery had significantly higher mortality compared with a matched control population undergoing similar procedures.[196] The high surgical risk in patients with irradiation-associated heart disease should be carefully considered when planning surgical interventions.

Arrhythmias

A full spectrum of cardiac arrhythmias and conduction disturbances have been reported in childhood cancer survivors treated with both irradiation and anthracyclines. These include atrioventricular nodal bradycardia, sick-sinus syndrome, complete and incomplete heart block, prolonged QT interval, and serious ectopy (ventricular tachycardia).[197] In a series of 48 survivors of pediatric Hodgkin lymphoma treated with mediastinal irradiation (median dose, 40 Gy), 75% were found to have conduction abnormalities.[198] The most frequent conduction disturbance was right anterior bundle branch block, the most anterior structure in the conduction system.[198] These arrhythmias are rarely symptomatic; however, the clinical concern is that conduction abnormalities may be progressive.[197,198] Because conduction abnormalities typically are asymptomatic, they usually are detected in association with other irradiation-induced cardiac abnormalities.[197,198]

Valvular Disease

The mitral, aortic, and tricuspid valves can all be affected by irradiation-associated fibrous endocardial thickening.[199] Valvular insufficiency is more common than valvular stenosis, but stenosis tends to be more severe, requiring intervention.[43,199,200] The frequency of left-sided valvular regurgitation is reported to be 16% to 24% in chest-irradiated survivors of Hodgkin lymphoma screened by echocardiography at a median of 10 years, and valvular dysfunction was not observed at a radiation dose less than 30 Gy.[200,201] In a cohort of 48 long-term survivors of pediatric Hodgkin lymphoma (median age at diagnosis, 16 years; median dose, 40 Gy), left-sided regurgitation was noted in 36% and valvular defects were detected in 42%.[198] In a recent report, the 30-year cause specific cumulative incidence of symptomatic valvular disease in survivors treated with cardiac irradiation was 2.5% (95% CI, 0% to 5.0%), compared with 0.1% (95% CI, 0% to 0.3%) for those treated without cardiac irradiation.[36] Valvular defects can be progressive, which is of particular concern for young survivors.[199] In a single-institution series of 415 survivors of Hodgkin lymphoma who received mediastinal irradiation, clinically significant valvular dysfunction developed in 6.2% at a median of 22 years.[43] In this cohort, aortic stenosis was the most common clinically significant valve lesion and when results were compared with those of an age-matched general population the relative risk for needing valve surgery was eightfold higher in survivors. The only treatment risk identified for significant valvular disease in this cohort was irradiation technique that resulted in a higher total dose to the heart.[43] Symptoms of valvular heart disease are the same in survivors as the general population, and valve function can be monitored by routine echocardiographic screening.

Pericarditis

The incidence of late-occurring irradiation-associated pericarditis has been significantly reduced by modern irradiation techniques.[202,203] In historic cohorts of children treated with orthovoltage mediastinal irradiation, 7% to 15% developed symptomatic constrictive pericarditis,[203,204] compared with 0% to 2.5% of children treated with megavoltage therapy.[203,205,206] Although the incidence of pericarditis has been significantly reduced in recent cohorts, older childhood cancer survivors continue to be at risk for pericarditis. Presenting signs and symptoms include pleuritic chest pain, shortness of breath, a friction rub, and electrocardiographic changes. A survivor presenting with symptomatic pericarditis is at risk for progressing to cardiac tamponade.[198] Management includes pericardiocentesis and pericardiectomy,[203] which are high-risk procedures in this patient population with known risks for other irradiation-associated cardiac morbidities.

Cerebrovascular Disease

Survivors treated with irradiation to the head and neck are at risk for the development of clinically significant premature cerebrovascular disease. Irradiation-induced cerebrovascular disease can encompass numerous abnormalities, such as moyamoya disease, vascular malformations including venous-based cavernous malformations (cavernomas) or intracranial aneurysms, and extracranial internal carotid stenosis.[207] Abnormalities such as cavernous malformations may be asymptomatic and noted incidentally on follow-up imaging or may present as neurologic symptoms such seizures, headache, or with hemorrhage, potentially necessitating surgical interventions.[208] Intracranial aneurysms can be life threatening.[209] There are limited long-term data on the risk for late-occurring cerebrovascular disease in survivors of childhood cancer. Data from the CCSS, based on self-report, demonstrated an increased risk for stroke in survivors of brain tumors (RR, 29) and of leukemia (RR, 6.4) when compared with sibling controls, and risk for stroke was associated with a mean cranial irradiation dose greater than or equal to 30 Gy. In addition, among leukemia and brain tumor survivors who did not receive cranial radiation therapy, the risk for stroke remained significantly increased when compared with siblings.[210] CCSS data also demonstrate an increased risk for stroke among survivors of Hodgkin lymphoma (RR, 4.32), with mantle irradiation strongly associated with subsequent stroke.[211] Importantly, in the CCSS cohort, smoking was associated with a threefold excess risk for stroke in survivors of Hodgkin lymphoma. In a study investigating cerebrovascular mortality in a French/United Kingdom cohort of 4227 five-year survivors of childhood cancer, at a median follow-up 29 years after radiation to the brain, the risk for death from cerebrovascular disease increased linearly with local radiation dose to the prepontine cistern. Survivors who received greater than 50 Gy to the prepontine cistern had a notably increased risk for death from cerebrovascular disease (RR, 17.8).[212]

Risk-based surveillance for cerebrovascular disease currently includes careful assessment by history and physical examination for neurologic and neurocognitive signs and symptoms. Neuroimaging is indicated for diagnostic assessment in symptomatic patients. The Children's Oncology Group Guidelines recommend consideration of baseline Doppler ultrasonography of carotid vessels 10 years after radiation therapy to the neck in those with radiation exposure of more than 40 Gy.[89] In a report on 30 childhood cancer survivors who received neck irradiation, Meeske and colleagues noted an increase in carotid disease on carotid ultrasound assessment compared with healthy control subjects, including in those treated with lower doses of radiation (18 to 30 Gy).[213] Further investigations are needed to better define risks and to inform screening recommendations. Abstinence from smoking should be emphasized. Aggressive medical management of other risk factors associated with cerebrovascular disease in the general population should also be advised.

Modifiable Cardiovascular Risk Factors

As noted earlier, attention to modifiable cardiovascular risk factors, such as obesity, hypertension, diabetes mellitus, dyslipidemia, and smoking, may be particularly important in the care of survivors of childhood cancer. A recent assessment from the CCSS found that two or more cardiovascular risk factors were reported by 10.3% of survivors. In this report, acquisition of modifiable cardiovascular risk factors, particularly hypertension, increased the risk for severe, life-threatening, and fatal cardiac events.[214] These results reinforce the importance of early diagnosis and careful management of modifiable cardiovascular risk factors in survivors.

Pulmonary System

Pulmonary toxicities as a consequence of cancer-directed therapy can range in severity from asymptomatic abnormalities on pulmonary function testing to life-threatening disease. Childhood cancer survivors are at increased risk for death from pulmonary complications. In an analysis of late mortality among 5-year survivors from the CCSS cohort, childhood cancer survivors were 8.8 times more likely to die of a pulmonary event compared with the U.S. population (age-, calendar year-, and sex-matched).[21] Therapeutic exposures, including radiation therapy, certain chemotherapeutic agents (bleomycin, carmustine, lomustine, busulfan, and cyclophosphamide), thoracic surgery, and hematopoietic stem cell transplantation, are associated with late pulmonary complications.[215] Recognition of these toxicities informed changes in upfront cancer-directed therapies, such as the reduction or elimination of radiation therapy and bleomycin in the treatment of Hodgkin lymphoma.

The late effects of radiation therapy on the respiratory system include reduced lung volumes, pulmonary fibrosis, and decreased chest wall growth. Risk factors for radiation-induced pulmonary late effects include concurrent pulmonary toxic chemotherapy, lung radiation dose greater than 15 Gy, spinal irradiation, and total-body irradiation.[216-218] Data from the CCSS cohort showed an increased risk for pulmonary fibrosis (RR, 4.3), emphysema (RR, 2.0), abnormal chest wall development (RR, 5), and chronic pneumonia (RR, 2.2) in those survivors who had chest irradiation. At 20 years after diagnosis, chest irradiation was associated with a cumulative incidence of pulmonary fibrosis of 3.5%.[219]

Treatment with chemotherapy including bleomycin, busulfan, cyclophosphamide, and nitrosoureas is also associated with the development of pulmonary fibrosis.[215,220,221] In the CCSS cohort, an increased risk for pulmonary fibrosis was seen in those exposed to bleomycin (RR, 1.4), carmustine (RR, 1.6), and busulfan (RR, 2.1).[219] A plateau in cumulative incidence of pulmonary fibrosis was not observed up to 15 years after diagnosis in survivors treated with chemotherapy alone or in combination with radiation therapy.[219]

Current long-term follow-up guidelines include obtaining a baseline chest radiograph and pulmonary function testing, including spirometry and diffusing capacity, in survivors with significant risk factors for late pulmonary toxicity.[89] Attention to smoking abstinence and cessation is also recommended. Reports of worsening bleomycin-associated pulmonary fibrosis after exposure to 100% oxygen suggest that survivors receive a pulmonary evaluation before undergoing anesthesia and avoid situations with increased oxygen concentrations such as scuba diving.[222]

Endocrine System

Hypothalamic-Pituitary Dysfunction

Hypothalamic pituitary dysfunction is a potential late effect in childhood cancer survivors who undergo radiation therapy for CNS, orbital, facial, or nasopharyngeal cancers. CNS tumors of the optic pathway, hypothalamus, or suprasellar region can also cause long-term hypothalamic-pituitary dysfunction as a result of hypothalamic injury from tumor growth or surgical resection. The incidence of pituitary hormone deficiencies after cranial irradiation varies by radiation dose and other treatment factors, such as age at therapy and duration of follow-up.[223] The reported range in prevalence of anterior pituitary deficiencies after a median dose of 45 to 55 Gy cranial radiation is as follows: growth hormone (GH), 85% to 100%; TSH, 3% to 60%; luteinizing hormone/follicle-stimulating hormone (LH/FSH), 5% to 40%, and adrenocorticotropic hormone, 4% to 30%.[223] This variability is a result of differences in cohort composition as well as different measures used to define hormone deficiencies. The GH pathway is the most sensitive to radiation and, therefore, GH deficiency is the most likely manifestation of hypothalamic hypopituitarism in survivors treated with cranial irradiation. The pituitary-thyroid, gonadal, and adrenal axes are less sensitive to late onset radiation toxicity, and, as such, centrally mediated deficiencies of these hormones are usually not observed in survivors treated with cranial irradiation below the range of 35 Gy.[186,224-228]

Growth Hormone Deficiency. The severity and latency of GH deficiency diagnosed in survivors is related to cranial irradiation dose. GH deficiency can be observed after doses as low as 18 to 24 Gy with late onset typically more than 10 years after therapy, whereas a cranial dose of more than 30 Gy can result in GH deficiency within 5 years after treatment.[229] This suggests that after a dose threshold of 18 to 25 Gy the incidence of GH deficiency increases with increased period of follow-up.[230,231] Clinical features of GH deficiency in survivors who have cranial irradiation can include poor growth, increased fat mass, reduction in lean body mass, decreased strength and exercise tolerance, adverse lipid profile, and decreased bone mineral density (BMD). These clinical features can be improved by GH replacement.[232] However, the use of GH replacement in GH-deficient survivors after they obtain final height is controversial, with more to be determined regarding the long-term benefits, safety, and risks for GH replacement in GH-deficient survivors in adulthood.[230,233]

The safety of GH replacement in childhood cancer survivors with regard to the risk for cancer recurrence or the development of a second primary cancer is controversial. Several studies report a lack of association between history of treatment with GH and primary cancer recurrence.[234-237] In a report from the CCSS, there was no documented increased risk for primary cancer recurrence in GH-treated survivors. However, exposure to GH was associated with an increased risk for second neoplasms (RR, 3.21; 95% CI, 1.88 to 5.46). An updated report from the CCSS continued to demonstrate this association (RR, 2.15; 95% CI, 1.33 to 3.47).[235,238] The association between development of second cancers and GH treatment is based on relatively few events and could be confounded by ascertainment bias (GH-treated patients could have had increased surveillance) and suggests the need for further study. The frequency and duration of screening for GH deficiency in childhood cancer survivors, the long-term effects and safety of GH replacement therapy, and the utility of long-term replacement therapy beyond attainment of final height require further investigation.

Skeletal Toxicities

Skeletal toxicities, including low BMD and osteonecrosis are increasingly recognized potential complications of therapy for childhood cancer. In children and adolescents undergoing treatment for cancer, acquisition of peak bone mass may be compromised. Cancer-directed treatment exposures, nutritional deficiencies, or physical inactivity can all contribute to decreased BMD in the setting of treatment of childhood cancer.[239] Risk factors for low BMD identified in cohorts of childhood cancer survivors include prior treatment with corticosteroids, methotrexate, cranial irradiation, and total-body irradiation. Survivors with hypogonadism, nutritional deficiencies, and prolonged immobilization or physical inactivity are also at risk for low BMD.[240-243] In the general population, osteoporosis-associated fractures result in significant morbidity and mortality; however, the association between low BMD and fracture risk has not been established for childhood cancer survivors. A report from the CCSS did not note an increased prevalence of fracture in adult survivors of childhood cancer compared with siblings[244]; however, the risks for long-term skeletal morbidity with advancing age remain to be defined.

Baseline bone density evaluation has been advised upon entry into survivorship care for those with treatment exposures associated with low BMD.[89] Dual-energy x-ray absorptiometry (DXA) is a commonly used modality that provides quantitative measurement of bone mineral content and indirect calculation of BMD. DXA has well-established normative pediatric values. However, as a two-dimensional technique, DXA has limitations and cannot provide direct volumetric measurements of BMD and is confounded by bone size.[245] Use of other modalities such as quantitative computed tomography (QCT) has been largely investigational.[246] Nutritional counseling to ensure sufficient intake of calcium and vitamin D in the diet, and supplementation in the setting of inadequate intake, has been recommended.[239] Management of conditions associated with decreased BMD, such as GH deficiency and hypogonadism, could potentially enhance bone health; however, the overall potential risks and benefits of such interventions with limited available data on long-term bone health outcomes must be considered.

Childhood cancer survivors are at increased risk for the development of osteonecrosis (also referred to as avascular necrosis). Osteonecrosis typically effects weight-bearing joints and can result in pain, loss of function, and joint collapse requiring surgical intervention including joint replacement. Cancer treatment exposures associated with the development of osteonecrosis include glucocorticoid therapy and irradiation,[247-249] with several studies indicating that exposure to dexamethasone is associated with a greater risk for osteonecrosis than exposure to prednisone.[249,250] Treatment as an adolescent has consistently been identified as a risk factor for the development of osteonecrosis.[249,250] Osteonecrosis has been identified as an acute toxicity of cancer therapy, with potential long-term impact on the quality of life of survivors. In the CCSS cohort, the 20-year cumulative incidence of osteonecrosis was 0.43%, with survivors 5.6 times more likely to have reported osteonecrosis compared with siblings. The risk for osteonecrosis was greatest among survivors of allogeneic stem cell transplant for underlying diagnoses of leukemia and in survivors of acute lymphoblastic leukemia, acute myelogenous leukemia, and bone sarcoma.[249] In this study, the cumulative incidence of osteonecrosis increased with time after treatment. Whether this reflects the worsening of previously asymptomatic bony lesions or a continued risk for the development of new lesions over time is unclear. Indeed, data are limited on the longitudinal outcomes of those diagnosed with osteonecrosis and more remains to be determined about the risk for late-occurring osteonecrosis.

In addition, bone and soft tissue in treatment fields are vulnerable to irradiation-induced hypoplasia and fibrosis, resulting in reduced or uneven skeletal growth. Survivors treated with irradiation that included the spine (>12 Gy) and long bones are at risk for scoliosis, shortened trunk height, and growth asymmetry.[251,252]

Disorders of Glucose Metabolism

Survivors of childhood cancer appear to be at increased risk for the development of insulin resistance and diabetes mellitus (DM). In a cross-sectional evaluation of survivors of childhood acute lymphoblastic leukemia, Oeffinger and colleagues noted that survivors of this type of leukemia treated with and without cranial irradiation had an increased prevalence of insulin resistance when compared with a cohort composed of older individuals from the same community.[253] In a report from the CCSS, the prevalence of DM was almost twice as high in childhood cancer survivors compared with siblings, with an increased risk for DM associated with total-body irradiation (OR, 7.2; 95% CI, 3.4 to 15; P <.001), abdominal irradiation (OR, 2.7; 95% CI, 1.9 to 3.8; P <.001), and younger age at diagnosis.[254] This increased risk for DM with abdominal radiation exposure in this cohort appeared to be independent of body mass index (BMI). Survivors of acute lymphoblastic leukemia who had cranial irradiation were 1.6 times as likely as siblings to report DM (after adjustment for BMI). [254] Survivors treated with total-body irradiation or with abdominal irradiation have been reported to have an increased risk for DM in several recent reports.[254-257] A report of 2520 survivors from France and the United Kingdom demonstrated a dose-response relationship between irradiation to the tail of the pancreas, where beta cells are concentrated, and risk for DM (RR of DM, 11.5% [95% CI 3.9 to 34] with 10 Gy or more to the tail of the pancreas).[257] Irradiation to other part of the pancreas was not associated with an increased risk for DM in this study. Further investigation of the mechanisms of development of DM and the interplay between treatment-related and modifiable risk factors in survivors is needed. Screening for DM should be considered in survivors, with implementation of aggressive risk-reduction strategies as clinically indicated.

Thyroid Disorders

The thyroid gland is extremely sensitive to radiation toxicity; subsequently, thyroid abnormalities are among the most common irradiation-induced morbidities after childhood cancer therapy. Childhood cancer survivors exposed to thyroid radiation as a consequence of direct neck irradiation for Hodgkin lymphoma, sarcomas, nasopharyngeal or oropharyngeal carcinomas, and other tumors are at risk for thyroid abnormalities. The clinical manifestations of thyroid irradiation injury include hypothyroidism, hyperthyroidism, thyroid nodules, and thyroid cancer. Because even low doses and scatter radiation can damage thyroid tissue, survivors who received seemingly distant irradiation such as whole-lung irradiation, craniospinal irradiation, and total-body irradiation for bone marrow transplant are also at risk for thyroid abnormalities. In addition, neuroblastoma survivors treated with ^{131}I-MIBG are at risk for hypothyroidism.[92,258] Although coadministration of potassium iodide is considered protective, a single-institution follow-up study of 16 survivors, a median 15 years after treatment, found 8 of 16 with clinical hypothyroidism. Primary hypothyroidism (low thyroxine [T_4] level with elevated TSH or compensated normal T_4 with elevated TSH) is the most common thyroid abnormality observed after thyroid irradiation.[93] Survivors in the CCSS cohort had a seventeenfold increased risk for hypothyroidism, compared with siblings.[93] The incidence of hypothyroidism increases with increasing radiation dose to the thyroid; at 20 years after treatment with 35 to 44.99 Gy the cumulative incidence is 35%, and with 45 Gy or more the cumulative incidence is 50%.[93] Risk factors identified for hypothyroidism are larger dose of radiation, older age at diagnosis, and female gender.[93] Although the greatest risk for hypothyroidism occurs the first 5 years after treatment, no plateau for thyroid disease has been observed and cumulative incidence continues to rise beyond 20 years of follow-up.[93] Central hypothyroidism (low TSH, low T_4) can be observed as a late toxicity of cranial irradiation to the hypothalamic pituitary axis, although centrally mediated deficiencies are usually not observed in survivors treated with cranial irradiation below 35 Gy.[224,226,229] Hyperthyroidism is an uncommon late effect and is sometimes observed after high-dose thyroid irradiation greater than 35 Gy.[93] Irradiation-induced thyroid nodules are commonly detected in survivors treated with head and neck irradiation. A recent cohort study of over 3000 survivors reported the cumulative incidence of irradiation-associated thyroid adenomas as 5.5% (95% CI, 4.2 to 7.2) at 40 years of follow-up.[259] A small cohort study of Hodgkin lymphoma survivors reported the median latency of thyroid nodules as 10 years (range, 1 to 25 years) after therapy, and in this study only 10% of nodules detected by physical examination or screening ultrasonography were malignant.[107]

Recommended screening for survivors at risk for irradiation-associated thyroid disease include annual palpation of the thyroid by a skilled examiner and annual measurements of serum thyroid hormones beginning 1 year after completion of therapy.[89,93] Thyroid replacement therapy is successful in treating irradiation-associated hypothyroidism. Treatment with thyroxine to suppress elevated TSH may reduce the frequency of benign nodules.[260] Routine ultrasound screening of asymptomatic survivors is controversial, because the majority of thyroid nodules detected in survivors have an indolent course and a minority of the nodules are malignant.[107] Survivors with palpable thyroid nodules are advised to undergo high-resolution thyroid ultrasonography with fine-needle aspiration of any large or suspicious nodules. Nodules with benign pathology can be followed by serial ultrasonography and resampled if there is interval change, and patients whose nodules that have indeterminate or malignant pathology are referred for thyroidectomy. Total thyroidectomy is often recommended to survivors because irradiation-associated thyroid cancers can be multicentric, the remaining thyroid is at risk for malignancy, and occult malignancy has been detected in nodules believed preoperatively to be benign.[108]

Parathyroid Disorders

Neck irradiation is associated with an increased incidence of hyperparathyroidism. Studies of adults treated with head and neck irradiation for nonmalignant conditions during childhood show a 2.5-fold increased risk for hyperparathyroidism, with a prolonged latency of 25 to 50 years.[223,261-263] Hyperparathyroidism was diagnosed in 10% (5/53) of childhood cancer survivors treated with head and neck irradiation who underwent surgery for thyroid disease at a single institution, with a latency of 15 to 34 years.[264] Survivors treated with neck irradiation as children should have monitoring of their serum calcium concentration as they approach older adulthood, especially if they have thyroid disease.

Short Stature

Many factors can contribute to growth disturbances in childhood cancer survivors, and it may be challenging to isolate a specific cause for diminished height in an individual child. Final height in survivors can be directly affected by cancer therapy and indirectly affected by treatment-related hormonal deficiencies and poor nutrition. Identified independent risk factors for diminished final height in childhood cancer survivors include treatment with cranial irradiation (related to GH deficiency), treatment with total-body irradiation, treatment with spinal irradiation, and young age at diagnosis (<age 13 years, with children <age 4 years at greatest risk).[265-269] Survivors of pediatric brain tumors and of leukemia who undergo cranial or craniospinal irradiation are at particular risk for short stature. In a report from the CCSS, among survivors of acute lymphoblastic leukemia significant risk factors for short stature included diagnosis before puberty, female sex, higher-dose cranial radiation therapy (≥20 Gy), and irradiation of the spine.[270] In a CCSS report assessing 921 brain tumor survivors, nearly 40% of survivors were below the 10th percentile for height. Risk factors included earlier age at diagnosis and higher doses of radiation therapy to the hypothalamic-pituitary axis.[267]

Irradiation-associated bone hypoplasia and fibrosis can directly impede skeletal growth, such that radiation fields that include the spine or lower extremities can result in diminished adult final height.[267,271,272] Irradiation-associated spinal deformities (kyphosis or scoliosis) can also impact final adult height.[251,252,271,272] Prolonged use of corticosteroids can impair longitudinal growth and reduce final adult height. Proposed mechanisms of corticosteroid-induced growth suppression include suppression of pituitary growth hormone secretion, reduction of insulin-like growth factor type 1 production by the liver, and possibly impaired action of insulin-like growth factor type 1 on bone, all of which contribute to diminished growth.[241,271,273] Antimetabolite chemotherapy is associated with decreased bone growth and diminished final height in some clinical studies.[241] This finding is supported by animal and in vitro models, which demonstrate that antimetabolite chemotherapy damages growth plate chondrocytes and impairs growth.[274]

Loss of height velocity during a prolonged course of treatment without subsequent catch-up growth can also result in diminished final attained height. Interruption of growth during the active treatment period can be related to the malignant process itself, poor nutrition, or growth suppression by therapy.[266,275] In a single-institution study of final height in survivors of childhood acute lymphoblastic leukemia, decrease in height growth scores in children undergoing active treatment was noted as soon as 6 months after beginning therapy.[266]

Treatment-induced deficiencies of GH, thyroid hormone, testosterone, and estrogen can all contribute to reduced final height in survivors. The effect of hormone deficiencies on final height can be minimized by early recognition and use of hormone replacement therapy.[276,277] Precocious puberty, a late effect observed after cranial irradiation, can also indirectly result in diminished final height because early onset of puberty reduces the time interval of prepubertal growth.[278] Cranial irradiation for CNS leukemia prophylaxis (18 to 24 Gy) is associated with relatively early and precocious puberty in girls, and higher doses of cranial irradiation often used to treat brain tumors can precipitate early puberty in both males and females.[278]

All childhood cancer survivors, and especially survivors exposed to therapies particularly associated with growth impairment such as total-body irradiation and cranial irradiation, should be monitored for appropriate growth during and after therapy.

Obesity

Obesity has been reported as a potential late complication in survivors of childhood cancer. Obesity is frequently defined as a BMI greater than the 95th percentile for age, or greater than or equal to 30 after age 21 years.[279] Irradiation-induced hypothalamic damage has been implicated in the pathogenesis of obesity in childhood cancer survivors, resulting in impaired growth, low metabolic rate, altered body composition, and dysregulation of eating behaviors.[265,280,281] Indeed, cranial irradiation has been identified as a risk factor for obesity in adult survivors of acute lymphoblastic leukemia.[282,283] A study of 1765 young adult acute lymphoblastic leukemia survivors enrolled in the CCSS identified female gender (RR, females 2.6, males 1.9), younger age at diagnosis in females (<4 years of age), and treatment with a radiation dose greater than 20 Gy during cranial irradiation as risk factors for obesity.[282] Treatment with lower-dose radiation therapy or chemotherapy only was not associated with an increased risk for obesity in this study. In a follow-up longitudinal analysis of changes in obesity and BMI among adult survivors of acute lymphoblastic leukemia from the CCSS, survivors treated with cranial radiation therapy had a significantly greater increase in BMI when compared with the sibling cohort. The rate of increase was not significantly increased for survivors treated with chemotherapy alone.[283] In contrast, a prospective study measuring BMI of 422 children with acute lymphoblastic leukemia and non-Hodgkin lymphoma before, during, and after completion of therapy found no difference in the rate of BMI increase between irradiated and nonirradiated children and concluded that high BMI at diagnosis was the best predictor of adult obesity in survivors of these malignancies.[284]

Physical inactivity as a consequence of treatment-associated morbidities, including cardiopulmonary disease that limits exercise tolerance, neurocognitive disabilities that limit coordination and participation, chronic pain, genetic factors, and social factors, all likely contribute to the obesity observed in survivors. Green and colleagues assessed risk factors for obesity among 9284 adult CCSS participants. In a multivariable analysis, impaired physical function, hypothalamic/pituitary irradiation, use of paroxetine, and younger age at cancer diagnosis were each independent predictors of obesity, whereas meeting the Centers for Disease Control and Prevention guidelines for physical activity and a reported moderate amount of anxiety were associated with a reduced risk for obesity. This study, including the findings of an association of a specific antidepressant and of poor physical functioning with obesity, highlights the importance of further investigation of the interplay between obesity, pharmacologic exposures, physical activity, and other modifiable risk factors.[285] Survivor care should include education regarding the long-term health consequences of obesity and the reduction of modifiable risk factors for this late effect.

Metabolic Syndrome

An increased risk for metabolic syndrome and/or its component parts has been observed in survivors of childhood cancer.[286-288] Metabolic syndrome is a grouping of component physiologic disturbances that is associated with an increased risk for developing cardiovascular disease and diabetes mellitus. Although there are various definitions of metabolic syndrome in the literature, definitions generally include measures of obesity, insulin resistance, dyslipidemia, and hypertension.[289] Identified treatment-related risk factors associated with metabolic syndrome in childhood cancer survivors include cranial irradiation and total-body irradiation.[287,288] Older attained age and a sedentary lifestyle have also been implicated.[290] Because metabolic syndrome is an established risk factor for cardiovascular disease and diabetes mellitus in the general population, aggressive management of modifiable cardiovascular risk factors in survivors is warranted.

Central Nervous System

Therapy for childhood cancer can result in long-term adverse sequelae on function of the CNS and sensory organs. Surgery, radiation therapy, and chemotherapy used to treat brain tumors and solid tumors in the head and neck region and cranial irradiation and chemotherapy used as CNS prophylaxis for leukemia and lymphoma can all contribute to neurologic, cognitive, and sensory deficits observed in survivors.

Neurocognitive Impairment

There is a broad spectrum of neurocognitive impairments observed in childhood cancer survivors. These include deficits in executive functioning (planning and organization), sustained attention, memory (visual sequencing and temporal memory), processing speed, visuomotor integration, and diminished intelligence. As a result of these deficits, survivors may experience learning difficulties, academic failure, and behavioral changes.[38,291-297] Neurocognitive impairment is observed in survivors treated with cranial radiation. Methotrexate, administered intrathecally as CNS prophylaxis or at high doses systemically (single dose >1000 mg/m^2), is also associated with neurocognitive late effects.[291,298] Indeed, neurocognitive impairment has been noted in adult survivors of acute lymphoblastic leukemia treated with chemotherapy alone (without cranial irradiation).[299] Brain tumor survivors treated with surgery alone are at risk for neurocognitive impairment attributable to direct brain injury from tumor growth, surgical resection, hydrocephalus, and seizures.[300]

Risk factors for neurocognitive impairment in childhood cancer survivors treated with radiation include higher dose, young age at exposure (<3 years), female gender, and personal or family history of learning disabilities.[38,293-295,301,302] Additional risk factors include total-body irradiation exposure and concurrent treatment with dexamethasone, methotrexate, or cytarabine.[293] Lower-dose cranial irradiation as CNS prophylaxis for leukemia/lymphoma (18 to 24 Gy) is more commonly associated with information processing or learning disabilities,[38] whereas higher-dose cranial irradiation necessary to treat brain tumors is more often associated with global cognitive impairments and diminished intelligence.[294] Neurocognitive deficits are persistent,[299] and new deficits may emerge over time or become evident during periods of increasing cognitive demands.[293] Armstrong and colleagues reported that adult survivors of childhood acute lymphoblastic leukemia who received 24 Gy of cranial irradiation had increased immediate and delayed memory impairment. In addition, survivors who received 24 Gy of cranial irradiation were found to function at a level one to two decades older than their chronologic age on delayed memory assessments, raising concern for early onset of cognitive impairment.[303]

Formal neurocognitive testing is used to diagnose cognitive impairments. A full battery of tests administered by specially trained psychologists is indicated to evaluate the full spectrum of potential deficits. Survivors diagnosed with neurocognitive impairments should be referred to specialized services at the treating center or in the community to facilitate access to educational, rehabilitation, social, and vocational resources. Cognitive remediation, educational interventions with individualized learning programs, and family support that address survivor specific needs are all necessary for survivors to meet full educational potential.[293,304]

Neurologic Deficits

Surgery for brain tumors and head and neck cancers can result in permanent neurologic deficits that are specific to the location of the primary cancer. For example, postoperative cerebellar mutism may persist years beyond the surgical resection of a posterior fossa tumor.[305] In addition, postoperative hydrocephalus, infections, and seizures can evolve into chronic neurologic conditions that result in neurologic deficits that can be stable or progressive over time.[40]

Peripheral sensory and motor neuropathy presenting as weakness, paresthesias, or pain and episodic vasospasm of the digits (Raynaud phenomenon) are potentially late effects associated with vincristine and vinblastine therapy.[306-308] Treatment-induced neuropathy might restrict survivors from physical activity; however, impaired motor performance, measured in a cohort of 128 childhood cancer survivors, was not associated with cumulative vincristine dose,[309] nor was prolonged vincristine exposure associated with physical inactivity observed in acute lymphoblastic leukemia survivors in the CCSS cohort.[310] Management of these late effects is primarily symptomatic, and a trial of agent used to treat neuropathic pain or prevent peripheral vascular spasm can be considered.[89,306]

Irradiation-induced cerebrovascular disease, such moyamoya disease, vasculitis, and vascular malformations (venous-based cavernous malformations or intracranial aneurysms) have been reported.[207,311-313] Late onset of seizures was reported in 6.5% of brain tumor survivors in the CCSS cohort and cortical irradiation of greater than 30 Gy was associated with a twofold risk for this complication.[40] Also in the CCSS cohort, an increased risk for late-occurring stroke was reported among survivors of brain tumor (RR, 29), leukemia (RR, 6.4), and Hodgkin lymphoma (RR, 4.32).[210,211] Rare neurologic late effects of radiation therapy associated with higher doses of radiation (>50 Gy) include focal brain necrosis and spinal cord myelitis.

Leukoencephalopathy, presenting as spasticity, ataxia, dysarthria, dysphagia, hemiparesis, or seizures, is a rare complication of treatment of childhood cancer and has been associated with cranial irradiation with doses of radiation greater than 18 Gy as well as chemotherapy with methotrexate and dexamethasone. Signs and symptoms of leukoencephalopathy may present without imaging abnormalities (brain MRI, MR angiography, CT); conversely, findings on neuroimaging (white matter changes, cerebral atrophy, dystrophic calcifications, mineralizing microangiopathy) do not necessarily correlate with clinical severity.[314-316] Leukoencephalopathy has also been described as a late manifestation of childhood histiocytic syndromes with no known treatment association.[317]

Late-onset neurologic complications can present as a variety of nonspecific neurologic symptoms, including headache, seizure, hemiparesis, or other focal findings. Neuroimaging is indicated for diagnostic assessment. Neurovascular abnormalities or irradiation-associated abnormalities of the brain parenchyma can also be incidental findings on neuroimaging obtained for other indications. The role of screening with neuroimaging in asymptomatic survivors is not yet defined, with no current data to support that screening asymptomatic survivors reduces morbidity or mortality from neurologic complications. However, cancer survivors who have received cranial irradiation and have nonspecific neurologic symptoms might benefit from early evaluation by a neurologist and/or early neuroimaging.

Vision

Childhood cancer survivors' vision may be impaired by surgery, localized irradiation, total-body irradiation, or chemotherapy with corticosteroids. Visual late effects are both anatomic and functional, including cataracts, orbital hypoplasia, lacrimal gland atrophy, conjunctival corneal damage, retinopathy, glaucoma, and optic nerve damage.[40,318-320] Cataracts are a visual late effect frequently diagnosed in bone marrow transplant survivors and survivors treated with cranial irradiation. Bone marrow transplant conditioning regimens that include total-body irradiation are associated with significant risk for cataract development that can require surgical intervention.[321,322] Chemotherapy-based conditioning regimens are not as likely to induce cataracts, and those that develop are usually less severe and do not requiring intervention.[321,322] Survivors with visual symptoms, those with a history of an ocular tumor, those who received total-body irradiation, or those treated with cranial, orbital, or ocular irradiation are at highest risk for late-onset ocular complications and should receive ongoing follow-up by an ophthalmologist.[40,89,320,321]

Hearing

Hearing loss is a late effect experienced by childhood cancer survivors exposed to head and neck radiation and/or platinum-based chemotherapy. Radiation fields that include the temporal bone and adjacent soft tissues can cause impaired auditory function.[40] Low-dose cranial irradiation alone (as was administered to leukemia patients) is unlikely to cause hearing loss; however, sensorineural hearing loss can occur at cranial doses greater than 50 Gy and at lower doses (40 to 50 Gy) when combined with ototoxic chemotherapy, especially when the treatment sequence is chemotherapy administered after irradiation.[40,323,324] In a series of 157 children with brain tumors treated by radiation therapy only with a median dose of 54 Gy, the cumulative incidence of hearing loss in the speech frequency range was 27% at 5 years after therapy.[325] The cumulative incidence of hearing loss steadily increased over the 9-year follow-up period, and no plateau was observed.[325]

The effect of platinum-based chemotherapy exposure on hearing is dose and age dependent. Children treated at a younger age (<5 years) are more vulnerable to cisplatin ototoxicity at any dose level.[326,327] The incidence of high-frequency hearing loss (4000 to 8000 Hz) is up to 50% in children treated with more than 450 mg/m^2 cumulative dose of cisplatin.[326] Hearing loss in the speech range (500 to 3000 Hz) is rarely reported at cumulative cisplatin doses less than 360 mg/m^2; however, it has been reported at cumulative doses as low as 360 mg/m^2, and the incidence is as high as 22% to 25% at cumulative dosages greater than 720 mg/m^2.[323,326] Cisplatin ototoxicity is typically bilateral and irreversible, and children with normal hearing at the completion of platinum therapy, who have not undergone cranial irradiation, are unlikely to have subsequent loss of hearing.[326] Survivors treated with carboplatin in nonmyeloablative doses do not appear to be at risk for hearing loss, but carboplatin-containing conditioning regimens used in stem cell transplant can contribute to hearing impairment.[328,329] Genetic polymorphisms associated with an increased risk for cisplatin-induced hearing loss in children have been identified.[44] Such findings await further validation but reflect a potential for tailoring treatment and/or follow-up based on the genetic risk for chemotherapy-associated ototoxicity.

The role of otoprotectants, such as amifostine, administered before or during cancer therapy, has not been established, and studies are ongoing in this area.[330] To minimize risk, clinicians should minimize exposure to other ototoxins, including aminoglycoside antibiotics and furosemide. In assessing a survivor, prior and current exposure to all ototoxic agents should be considered in the assessment of auditory function. The contribution of environmental factors (e.g., use of headphones, occupational exposures) to hearing loss in the young survivor population has not been documented.[329] Survivors with treatment exposures that put them at risk for hearing loss or those with symptoms of hearing impairment should have serial auditory evaluations, and those diagnosed with hearing impairments should be prescribed hearing aids and classroom or workplace accommodations as indicated. Early intervention for auditory problems is particular important in the survivor population because hearing loss has the potential to compound already existing social, developmental, and cognitive impairments.

Reproductive System

Reproductive function depends on the complex interaction of hormonal, anatomic, and psychosocial factors. Treatment of childhood cancer directed at the brain, spinal cord, pelvis, genitourinary organs, and gonads can all impair future reproductive potential. Therapy that is directly toxic to the ovaries and testes predisposes survivors to primary hypogonadism resulting in both diminished sex hormone production (testosterone, estrogen) and damage to oocytes and spermatocytes. Secondary hypogonadism, impaired secretion of gonadotropins (LH, FSH), can be the result of radiation and surgery to the hypothalamic-pituitary axis. Alternation of the neurovascular or structural anatomy of the reproductive organs or reduction in the volume of gonadal tissue by radiation and surgery can also impair reproductive function. As with most late effects, chemotherapy-associated gonadotoxicity is directly related to the individual agent and cumulative dose. Specifically, the alkylating agents cyclophosphamide and procarbazine pose a greater risk for gonadal dysfunction than cisplatin and dacarbazine.[35,331-333] In general, the ovary is less vulnerable to chemotherapy-induced damage than the testis. As with other late effects, irradiation-associated toxicity to the ovaries and testes is dependent on the radiation dose and field. The availability of established fertility preservation strategies for patients newly diagnosed with cancer (semen cryopreservation, oophoropexy, oocyte cryopreservation) may improve long-term fertility outcomes for survivors treated with gonadotoxic therapy.[334-337]

Females

Ovarian dysfunction can be a result of acute ovarian toxicity that persists or premature ovarian failure. The majority of prepubertal and adolescent girls receiving standard-dose chemotherapy will retain or recover ovarian function; however, those receiving high-dose alkylating agents, conditioning for bone marrow transplant, or those exposed to pelvic irradiation are at risk for irreversible ovarian toxicity, which manifests as both estrogen deficiency and infertility.[338-341] Of note, irradiation to the pelvis, abdomen, or spine may include the ovaries in the field. Ovarian doses greater than 10 Gy can result in complete ovarian failure, requiring hormone replacement therapy.[342,343] Survivors treated with both radiation therapy and gonadal-toxic chemotherapy have a worse prognosis for ovarian function.[344,345] Cranial irradiation that has a radiation dose greater than 22 Gy to the hypothalamic-pituitary access is associated with reduced fertility, and use of more than 30 Gy is associated with ovarian failure as a result of impaired secretion of gonadotropins (LH, FSH).[346] Survivors diagnosed with ovarian failure should be offered treatment with hormone replacement therapy in consultation with an endocrinologist.

Survivors who retain or recover ovarian function after completing therapy are at risk for premature menopause (defined as cessation of menses prior to age 45 years). Risk factors for premature menopause include increasing age, older age at treatment, increasing radiation dose to the ovaries, and increasing cumulative dose of alkylating agents.[344,345] The pathophysiology of therapy-induced premature menopause is reduction in number of ovarian follicles, which supports the finding that prepubertal girls with the greatest reserve of follicles are less vulnerable to premature ovarian failure than older survivors. In the historic Five-Center Study, which included 1067 female survivors, the risk for reaching early menopause (age <25 years) for those treated between the ages of 13 and 19 years was four times greater than sibling controls.[347] Increased risk for premature menopause was observed in survivors treated with irradiation below the diaphragm (RR, 3.7), alkylating agents (RR, 9.2), or both (RR, 27). In this historical cohort, 42% of women treated with irradiation below the diaphragm and alkylating agents had reached menopause by age 31 years.[347] The overall relative risk for premature menopause in survivors in the CCSS cohort was thirteenfold higher than sibling controls, with a cumulative incidence of 8% by age 40.[345] In this study, the cumulative incidence of menopause for survivors exposed to alkylating agents only was 5% at age 35 years and increased to 15% by age 40 years, and survivors exposed to both radiation therapy and alkylating agents had a cumulative incidence of menopause of 15% at age 30 years that increased to 30% by age 40 years.[345] Of note, the threshold dose of cumulative alkylating agent exposure below which ovarian function is preserved has not been determined, and in pelvic irradiation even the lowest radiation doses (1 to 99 cGy) are associated with premature menopause.[345]

Survivors who retain ovarian function but are at risk for premature menopause should be educated about their potentially reduced window of fertility and offered referral to fertility specialists for counseling and intervention. Clinical tests to predict the precise timing of menopause are not available; however, the serum antimüllerian hormone level is promising as a predictor of ovarian reserve and is likely to be recommended for routine monitoring of cancer survivors at risk for premature menopause in the near future.[341] Hormonal interventions to potentially prolong ovarian function have not been clinically effective.[341] Cryopreservation of embryos (which require a partner or sperm donor) is an option for a survivor who anticipates early menopause. Recent successes in the techniques of cryopreservation of eggs during the period of ovarian function create new options for survivors at risk for premature menopause.[341,348]

Males

Males treated with alkylating agents as children and adolescents are at risk for infertility secondary to impaired testicular germ cell function and low testosterone resulting from Leydig cell insufficiency.[349] Alkylating agent gonadal toxicity is dose dependent, and pubertal status or age at exposure is not protective.[35,225,350] Of note, the majority of male survivors with alkylating agent–induced infertility will have normal testosterone production, with normal sexual function and secondary sexual characteristics. Abnormal semen analyses have been observed with cumulative cyclophosphamide doses greater than 5.0 to 7.5 g/m^2. However, Leydig cell insufficiency (elevated serum LH, normal testosterone) or Leydig cell failure (elevated LH, low testosterone) is associated with higher total cyclophosphamide doses (>20 g/m^2).[35,351,352] Survivors treated with unilateral orchiectomy and not exposed to additional gonadal toxic therapy usually maintain adequate testicular function.[353]

A survivor's risk for irradiation-induced testicular dysfunction depends on radiation dose and age at exposure. Testicular germ cells are very sensitive to radiation damage. Changes in spermatogenesis can be observed after doses as low as 0.1 Gy, and irreversible azoospermia usually occurs after doses greater than 2 Gy.[339] In contrast, testosterone production is usually preserved with testicular doses up to 20 Gy. Irreversible damage to testicular germ cell and endocrine function usually occurs after exposure to more than 20 Gy of radiation, requiring androgen replacement therapy. However, survivors who are beyond puberty at the time of diagnosis can usually tolerate higher doses of radiation before loss of testicular endocrine function.[265]

Although reduced testicular volume on physical examination, elevated serum gonadotropins (e.g., FSH), and low serum inhibin B suggest infertility, the only definitive measures of a survivor's potential fertility is by semen analysis or paternity. Of note, male survivors with ejaculatory azoospermia diagnosed by semen analysis soon after completion of therapy have the potential to recover spermatogenesis many years later.[352,354] Thus a sexually active survivor who is not contemplating paternity must be counseled about birth control, even if he has had an abnormal semen analysis in the past. Furthermore, survivors with ejaculatory azoospermia who desire biologic paternity may be candidates for the surgical procedure of testicular biopsy with sperm extraction.[355] These men should be referred to a urologist with this expertise for consultation.

Survivors with delayed onset of puberty or symptoms of hypoandrogenism should be screened with morning serum testosterone, LH, and FSH evaluation. If results are abnormal, testosterone replacement therapy should be guided by the appropriate subspecialist. Of note, serum testosterone levels normally decline with advancing age, so survivors at risk for treatment-associated hypoandrogenism should have serum testosterone levels reevaluated as they reach older adulthood.

Sexual Function

Surgery or irradiation of the pelvis or lumbar spine, treatment-associated hormonal insufficiencies, medical comorbidities, and the social and emotional changes associated with a cancer experience may predispose childhood cancer survivors to sexual dysfunction. An emerging literature on the prevalence and risk factors for sexual dysfunction in young adult survivors of childhood cancer shows a higher than expected prevalence of both males (20% to 32%) and females (37% to 52%) reporting a problem in one or more areas of sexual function.[356-359] Normal sexual function is dependent on the complex interplay of both physical and social and emotional factors. Physical factors that can cause sexual dysfunction include disruption of normal pelvic anatomy from pelvic or spinal surgery or irradiation, hormonal deficiency, increasing age, and emotional distress.[349] Survivors at the greatest risk for psychosexual dysfunction include those diagnosed during adolescence, those with a brain tumor, and those with poor health status; these factors may be related to social isolation and delayed psychosexual development.[356,358,359] Because sexual function is an important aspect of quality of life and all survivors are at risk for psychosexual dysfunction related to their cancer experience, it is recommended that all adolescent and young adult survivors have an assessment of their sexual function as part of follow-up care.[360] The assessment for sexual dysfunction in the childhood cancer survivor includes a thorough psychosexual history, sexual history, medical history, and physical examination, including Tanner staging. Sexual history should include detailed questions about social relationships; body image; sexual experiences; libido; for women, lubrication genital sensation, orgasm, dyspareunia, and postcoital bleeding; and for men, nocturnal emissions, spontaneous erections, orgasm, and quality of ejaculate. If sexual dysfunction is a concern, consultation with gynecologist, urologist, or psychotherapist is indicated.

Pregnancy

Women who undergo abdominal or pelvic irradiation who are able to conceive children are at risk for complications of their pregnancy and delivery. Irradiation-induced damage to uterine muscle and blood flow adversely affects survivors' prognosis for a healthy full-term pregnancy.[361] Pelvic and abdominal radiation fields that include the uterus are associated with pregnancy complications, including spontaneous abortions, preterm labor, low-birth-weight infants, infants who are small for gestational age (SGA), neonatal death, and postpartum hemorrhage.[343,362,363,364-369] A report on more than 4000 pregnancies from the CCSS showed that the only risk factor for adverse pregnancy outcomes was pelvic irradiation, which was associated with low-birth-weight infants (RR, 1.84). No other treatment factor was a risk for any adverse pregnancy outcome in this large cohort.[362,363] When the analysis was restricted to 2201 liveborn children of 1264 survivors in the CCSS cohort, maternal uterine irradiation (>5 Gy) was associated with prematurity (OR, 3.5), low birth weight (OR, 6.8), and SGA infants (OR, 4.0).[364] Estrogen therapy does increase uterine size and stimulate blood flow but is not shown to improve uterine muscular function.[370]

Survivors with therapy-associated cardiac toxicity (either subclinical or overt) are at risk for pregnancy-associated congestive heart failure and should be monitored before pregnancy, during pregnancy, and after delivery by obstetricians aware of potential complications.[157,371] Peripartum acute congestive heart failure has been described in survivors treated with anthracyclines and chest irradiation; however, the incidence has not been determined.[157,371] One study of 37 anthracycline-exposed pregnant women showed that prepregnancy left ventricular dysfunction was a risk factor for acute congestive heart failure during pregnancy, supporting the need to closely monitor at-risk survivors.[371] Survivors with risks for other organ toxicities such as endocrinopathies, pulmonary fibrosis, and renal insufficiency should also be meticulously evaluated and monitored before pregnancy, during pregnancy, and after delivery.

Offspring

Many studies have investigated the possible association between exposure to cancer therapy during childhood and a mutagenic or teratogenic effect on future offspring. Fortunately, no study to date has found in increased risk for either congenital anomalies or cancer in the offspring of adult survivors of nonhereditary childhood cancer treated before conception,[35,372-381] This is true for both male and female survivors of childhood cancer and survivors treated with both chemotherapy and radiation therapy. Of note, survivors of childhood cancers that are associated with genetic syndromes and hereditary cancer predisposition (e.g., Cowden syndrome, Li-Fraumeni syndrome, retinoblastoma) are at increased risk for their offspring being diagnosed with cancer. These survivors should be referred for genetic counseling and genetic testing as desired and appropriate (see Box 72-2). Preimplantation genetic testing may be available to survivors with a known mutation in a cancer predisposition gene who are contemplating pregnancy.[382,383]

Renal System

Chronic renal disease is a late effect associated with irradiation to the kidneys as part of an abdominal field or total-body irradiation; chemotherapy with ifosfamide and high-dose cisplatin; nephrectomy, especially in combination with other nephrotoxic therapy; and treatment with other nephrotoxic agents, including antibiotics and immunosuppressants. The pathophysiology of irradiation injury to the kidney is progressive arteriolonephrosclerosis, resulting from irradiation injury of the renal microvasculature with subsequent secondary damage to the glomeruli and tubules. Irradiation-associated renal injury is dose related, and the threshold dose is approximately 15 Gy; however, nephrectomy and exposure to other nephrotoxic agents lower that threshold.[384,385] In a cohort of bone marrow transplant survivors treated with fractionated total-body irradiation, 12 to 14 Gy over 3 to 4 days, late renal dysfunction was reported in 35% of acute lymphoblastic leukemia survivors and 71% of neuroblastoma survivors.[385] Modern conditioning regimens with altered fractionation should reduce the incidence of renal insufficiency in transplant survivors.

Chemotherapy with cisplatin at doses greater than 200 mg/m^2 can cause nephropathy secondary to glomerular or tubular injury. This injury is usually acute and reversible; however, it can be stable or progressive.[386] Carboplatin does not appear to be associated with long-term nephrotoxicity.[387] Ifosfamide nephrotoxicity is also a result of glomerular or tubular injury and presents most often as renal tubular acidosis.[388] The greatest risk for ifosfamide nephrotoxicity is at total dose greater than 45 g/m^2, and age younger than 3 years.[388] Combination nephrotoxic chemotherapy, nephrectomy, and therapy with nephrotoxic antibiotics all contribute to survivors' risk for long-term renal damage.[389-392]

The risk for chronic renal disease in survivors treated with unilateral nephrectomy alone appears to be minimal.[393] However, data suggest that patients treated with unilateral nephrectomy do manifest subclinical evidence of early reversible renal injury detectable by elevated urine levels of microalbumin.[394,395] A study linking Wilms tumor survivors in the National Wilms Tumor Study group to the U.S. End-Stage Renal Disease registry followed for a median of 11 years showed a low risk for end-stage chronic renal failure in nonsyndromic Wilms tumor survivors (cumulative incidence, 0.6% at 20 years).[393] These data suggest that Wilms tumor survivors with clinically detectable renal dysfunction will not routinely progress to end-stage renal disease.[393] Of note, this cohort has not reached an age when survivors might be at the greatest risk for chronic renal failure.[393] Survivors of Wilms tumor with the highest cumulative incidence of chronic renal failure at 20 years are survivors with predisposition syndromes such as Denys-Drash syndrome (74%), WAGR syndrome (36%), genitourinary abnormalities (7%), and survivors with bilateral disease

(12%).[396-398] Survivors of Wilms tumor with progressive tumor in the contralateral kidney or nephrogenic rests and survivors who have undergone irradiation have also been identified as having an increased risk for renal dysfunction.[396-398]

Survivors treated with nephrotoxic therapy should be routinely monitored for early clinical signs of renal dysfunction, including hypertension, proteinuria, and elevated serum creatinine concentration. Survivors with the earliest signs of renal injury might benefit from therapeutic interventions with angiotensin-converting enzyme inhibitors to reverse or halt progression of renal injury. Survivors with a single kidney should be counseled to adopt health behaviors to maintain kidney health, including hydration, avoidance of prolonged use of nonsteroidal antiinflammatory drugs, prompt treatment of urinary tract infections, and meticulous control of coexisting diabetes and hypertension.

Genitourinary System

In addition to the renal late effects discussed previously, survivors of childhood cancer are also at risk for toxicity to the genitourinary system from surgery, treatment with pelvic and whole-abdominal irradiation, and alkylating agent chemotherapy. Genitourinary surgery can result in long-term functional impairments, including urinary incontinence and sexual dysfunction. The primary late effects associated with irradiation include fibrosis or hypoplasia of the anatomic components of the male and female genitourinary systems, including urinary bladder, ureter, urethra, prostate, vagina, and uterus, resulting in chronic pain or dysfunction. Survivors experiencing anatomic or functional genitourinary late effects, including sexual dysfunction, should be referred to a gynecologist or urologist as indicated for evaluation and management of their symptoms.

Chemotherapy with cyclophosphamide and ifosfamide has been associated with protracted hemorrhagic cystitis and bladder fibrosis, although this late effect has been reduced by concurrent therapy with mesna.[399,400] Hemorrhagic cystitis that develops beyond the time of therapy more often has a viral etiology or is associated with chronic graft-versus-host disease (GVHD) in transplant survivors.[401] Although the risk for bladder pathology in childhood cancer survivors is low, routine monitoring with urinalysis of survivors exposed to cyclophosphamide and ifosfamide is clinically indicated.

Gastrointestinal System

Potential late effects of cancer therapy on the gastrointestinal system are late onset surgical complications such as adhesions, small bowel obstruction, and fecal incontinence[402]; irradiation-induced functional impairment; and secondary neoplasms of the gastrointestinal tract and hepatobiliary system.[67] Hepatic fibrosis is a rare late complication of antimetabolite chemotherapy (methotrexate, mercaptopurine, thioguanine), and the fibrosis typically follows acute hepatic toxicity such as venoocclusive disease.[403-405] As with other organ systems, irradiation can result in functional impairment and second cancers of the gastrointestinal organs consequently exposed to radiation as a result of location in a treatment field. The clinical spectrum of irradiation-induced gastrointestinal toxicity that has been reported includes salivary gland dysfunction, esophageal stricture, Barrett esophagus, hepatic fibrosis and cirrhosis, focal nodular hyperplasia, cholelithiasis, and chronic enterocolitis.[405,406] In the CCSS, survivors had nearly twice the risk for gastrointestinal disease than that observed in the sibling cohort. Survivors were more likely to require colostomy/ileostomy (RR, 5.6 [95% CI, 2.4 to 13.1]), undergo liver biopsy (RR, 23.1 [95% CI, 7.5 to 77.8]), or self-report cirrhosis (RR, 8.9 [95% CI 2.0 to 40.0]).[407] Risk factors for gastrointestinal toxicity in long-term survivors included older age at diagnosis (>10 years), high-dose alkylating agent and/or anthracycline exposure, abdominal irradiation, and abdominal surgery.[407] Of note, survivors were more likely to have more than one gastrointestinal condition than their siblings and more frequently reported common conditions such as diarrhea, ulcers, polyps, and heartburn.[407]

Common gastrointestinal symptoms reported by a childhood cancer survivor, such as abdominal pain and heartburn, should be evaluated in the context of his or her treatment history. A survivor's risk for a serious gastrointestinal pathologic process should be considered when planning a diagnostic workup and therapy for common symptoms. Children requiring abdominal surgery as part of their cancer therapy are at risk for late onset small bowel obstruction and should be educated about his late effect.[408] Because survivors exposed to abdominal irradiation are considered to be at higher risk for colon cancer, and self-report polyps at greater frequency,[407] they are advised to begin colon cancer screening earlier than what is recommended for the general population (10 years after completing radiation therapy or age 35 years, whichever comes last).[67,89]

OTHER LATE EFFECTS

Infections

Late-occurring infectious complications can result from surgery, transfusions, immunosuppression, and radiation therapy. Childhood cancer survivors who had a surgical splenectomy as part of their staging for Hodgkin lymphoma are at lifelong risk for potentially fatal bacterial sepsis with encapsulated organisms. Survivors who received more than 40 Gy of abdominal or left flank irradiation are considered functionally asplenic and have a similar risk for sepsis.[409] These survivors must be continually reminded of their risk and educated to receive immediate medical evaluation and prophylactic antibiotic therapy for fever or other signs of sepsis. Immunizations against *Streptococcus pneumoniae, Haemophilus influenzae,* and *Neisseria meningitidis* are also recommended for this high-risk group.[410] Hematopoietic stem cell transplant survivors receiving immunosuppression for chronic GVHD are also at risk for ongoing infectious complication and should be considered for prophylactic antibiotics.[411] Older survivors treated in the United States are at risk for transfusion-acquired chronic hepatitis B if they received blood products prior to 1972; for hepatitis C if they received blood products prior to 1993; and for human immunodeficiency virus if they received blood products between 1977 and 1985.[412] Irradiation to the sinuses for a primary sarcoma or CNS tumor at doses greater than 30 Gy is associated with chronic bacterial sinusitis.[413] Survivors who received therapy that is associated with a risk for pulmonary disease such as lung irradiation or total-body irradiation and those with cardiac disease should receive annual influenza vaccine. Survivors with known irradiation-associated valve disease should receive appropriate antibiotic prophylaxis for subacute bacterial endocarditis.[414] Survivors at risk for infectious complications should be educated about their risks and informed of the necessity for preventive strategies.

Dental Problems

Childhood cancer survivors are at risk for dental late effects. Survivors treated with head and neck irradiation are at risk for root shunting, microdontia, hypodontia, and craniofacial abnormalities resulting in severe cosmetic or functional impairment necessitating surgical or orthodontic intervention.[415-417] The risk for dental facial abnormalities is greatest in survivors treated at the youngest age and with higher doses of radiation. Survivors treated with chemotherapy prior to the complete eruption of their permanent teeth are at risk for tooth agenesis, root thinning or shortening, and enamel dysplasia.[417,418] Neuroblastoma survivors and leukemia survivors treated with cranial irradiation have a particularly high incidence of dental abnormalities (71% and 94%, respectively) most likely associated with young age at treatment.[416,417] In a report from the CCSS, when compared with the sibling cohort, survivors were more likely to report microdontia, hypodontia, root abnormalities, abnormal enamel, teeth loss (six or more), severe gingivitis, and xerostomia. Radiation exposure of 20 Gy or more to dentition was associated with an increased risk for one or more dental abnormalities. Children diagnosed at age younger than 5 years treated with alkylating agents also had increased risk for one or more dental abnormalities.[419] All childhood cancer survivors should be advised to have regular dental care, including cleanings, fluoride applications, and appropriate imaging to evaluate tooth development.[89]

Psychosocial Function

The experience of having childhood cancer and its associated treatment can have long-term effects on a survivor's emotional and social functioning. Common disorders of emotional function, such as depression, anxiety, and posttraumatic stress disorders are reported more frequently in populations of childhood cancer survivors than in both their siblings and the general population.[420,421] Serious emotional distress, such as suicidal symptoms, is also reported more commonly in survivors. In a report from the CCSS, adult survivors of childhood cancer were at increased risk for suicidal ideation compared with the sibling control cohort (7.8% of survivors reported suicidal ideation compared with 4.6% of controls [OR, 1.79; 95% CI, 1.4 to 2.4]). In survivors, suicidal ideation was associated with a primary diagnosis of CNS malignancy, depression, and poor current physical health.[422] There is no known increased incidence of psychiatric disorders such as schizophrenia or other psychoses in childhood cancer survivors, with the exception of survivors of brain tumors. A Dutch study of over 3700 childhood cancer survivors found that brain tumor survivors had an excess risk for psychiatric hospitalizations for diagnoses that included psychoses of somatic and cerebral causes, psychiatric disorders in somatic disease, and schizophrenia.[423]

Challenges to normal social functioning such as educational remediation, employment discrimination, insurance discrimination, marital dissatisfaction, social isolation, and poor health-related quality of life have all been reported more frequently in survivors of childhood cancer.[424-433] The majority of childhood cancer survivors will not experience significant psychosocial dysfunction as a result of their cancer experience or cancer therapy; however, survivors of childhood CNS malignancies and those treated with cranial irradiation are more vulnerable to psychosocial morbidity. These survivors, in particular, should be routinely monitored for emotional distress and social disability.

SPECIAL CONSIDERATIONS FOR THE HEMATOPOIETIC STEM CELL TRANSPLANT SURVIVOR

The comprehensive clinical evaluation of the hematopoietic stem cell transplant (HSCT) survivor requires that the clinician consider all aspects of the survivor's pretransplant history, transplant course, posttransplant immune function, and disease status. In assessing the risk for late effects in a survivor of HSCT, both the treatments associated with the condition that led to the transplant and the therapies associated with the transplant must be considered. The modality, dose, and intensity of the conditioning regimens for HSCT are major factors that determine the survivor's risk for late effects. Total-body irradiation used as conditioning for HSCT may contribute to the organ-specific toxicity of prior chemotherapy, such as cardiotoxicity from anthracyclines,[188] ototoxicity from platinum agents,[324] and gonadotoxicity of alkylating agents.[344] The transplant history should be reviewed for complications that occurred during the course of transplant, such as acute pneumonitis or renal failure, which might add to the survivor's risk for late onset organ toxicity.[221,385] Survivors who received an allogeneic HSCT are at risk for chronic GVHD that can be associated with severe chronic illness. Long-term consequences of chronic GVHD can include joint contractures, polymyositis, vaginal stenosis, alopecia, vitiligo, scleroderma, lichenoid skin lesions, xerostomia, lichenoid or atrophic oral lesions, xerophthalmia, keratoconjunctivitis, esophageal strictures, malabsorption, cholestasis, bronchiolitis obliterans, and obstructive airway disease. Survivors with chronic GVHD and those on chronic immunosuppressive regimens have an increased risk for infection.[411] Comprehensive assessment of the HSCT must also include posttransplant immunization history to ensure revaccination was accomplished at appropriate intervals after transplant.

FOLLOW-UP CARE OF CHILDHOOD CANCER SURVIVORS

The need for specialized follow-up care for childhood cancer survivors is evident, given the numerous morbidities associated with childhood cancer treatment and the potential for survivors to develop complications decades after treatment. The prevalence of chronic health conditions observed in young adult survivors of childhood cancer is 62% in the CCSS cohort and 58% in a single-institution cohort of survivors from the United Kingdom.[46,434] In the CCSS, almost a third of patients had a severe or life-threatening health condition, and the cumulative incidence of a severe or disabling health condition approached 50% at 30 years after the diagnosis of childhood cancer.[46] A survivor's self-reported health status, including self-assessment of functional health, general health, mental health, and pain, has been described in several cohorts of young adult survivors of childhood cancer. Impaired health status is reported in more than 75% of adult survivors surveyed in Canada, 58% of adult survivors in a British cohort, and 48% of adult survivors in the CCSS.[434-436]

Although childhood cancer survivors are at risk for a variety of treatment-related health conditions as they age, they are not necessarily knowledgeable about the specifics of their cancer diagnosis and treatment, nor are they proactive about their future health or adherent to follow-up recommendations. Of the young adult survivors surveyed in the CCSS cohort, only 72% could accurately report their diagnosis; and although the majority were knowledgeable about the general type of therapy they received (e.g., chemotherapy, surgery, irradiation), only 70% of those receiving radiation therapy could report the site.[437] Furthermore, an analysis of cancer screening practices of the young adults in the CCSS cohort showed that adherence was not optimal[438] and in a separate analysis it was shown that the proportion of survivors who remain in long-term follow-up decreases with increasing years since completion of therapy.[439] The high prevalence of chronic health conditions, poor health status, knowledge deficits, and suboptimal adherence to follow-up recommendations all support the need for comprehensive specialized follow-up care of childhood cancer survivors, including both provision of health care services and risk education.

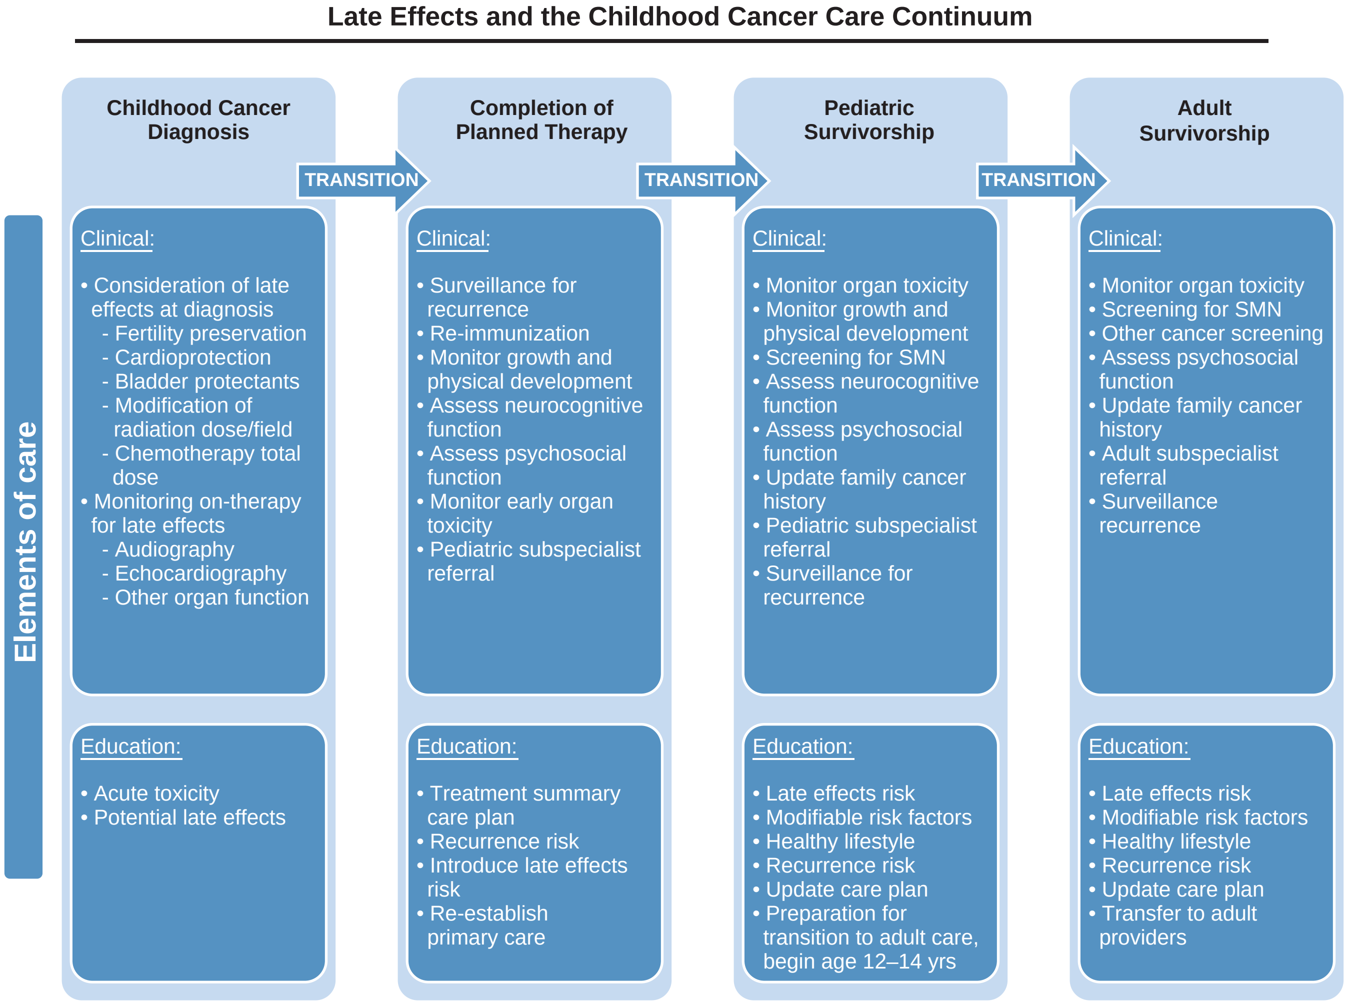
Models of Survivorship Care

Comprehensive survivor programs have been developed at pediatric cancer centers to provide long-term, specialized, risk-based, follow-up care to childhood cancer survivors. A survey of Children's Oncology Group institutions found 87% provide survivorship care and 59% have specialized late effects programs.[440] The ideal components of follow-up care systems include review of disease treatment and history, screening for and diagnosing late effects, a plan for long-term surveillance, coordination of subspecialists, provision of psychosocial support, counseling on education and occupation, coordination of transition to adult care, education and outreach to survivors in the community, education of professionals (primary care providers, educators), and research. The optimal patterns and models of care for childhood cancer survivors have not been well studied. A model endorsed by leaders of existing pediatric long-term follow-up clinics contains the following elements: clinic services under the direction by a pediatric oncologist with expertise in survivorship care; staffing by advanced degree nurses to provide and coordinate patient care; and access to social workers, psychologists, a referral network of medical and surgical specialists with survivorship expertise, and ongoing care provided in the community with periodic center-based follow-up.[441] This model assumes frequent bidirectional communication between survivors, primary care providers, and oncologists with clear delineation of responsibilities for ongoing care. In general, these comprehensive, center-based programs have the proven advantage of providing multidisciplinary expertise and survivor education and have the facility for research in cancer survivorship. Common challenges these programs face are limited financial and personnel resources; inadequate capacity to meet the needs of growing numbers of survivors; and limited access because of geography, insurance, or lack of awareness on the part of the primary care providers or the individual survivor.[441,442] These and other alternative models for extending and improving care delivered to childhood cancer survivors have been proposed but have not been formally evaluated in terms of feasibility and efficacy.

Current efforts to retain survivors in long-term follow-up have focused on introducing and reinforcing the concept of life-long follow-up at critical transition points on the cancer care continuum (Fig. 72-6). Two specific points that have become the focus of educational interventions are the time periods around completion of planned cancer treatment and again when a survivor is an emerging adult. Transition programs for those who recently completed therapy are designed to educate survivors regarding treatment-related risks and to introduce issues related to survivorship early after cancer treatment. The goal of these programs is to bridge the period between active therapy and survivorship follow-up care and subsequently reduce the knowledge deficit and loss to follow-up seen in prior cohorts of long-term survivors.[443] Similarly, transition programs for survivors who have reached the age of adolescence or young adulthood are designed to support adolescent or young adult survivors as they transfer care to adult-oriented health care services. Ideally, these transition programs address the transfer of knowledge about disease, treatment, and future health risks from parents to adolescent or young adult survivor; enhance the survivor's cognitive competence/self-efficacy; and help with access to and confidence in adult providers.[444] Research is needed to test the efficacy of these transition specific programs to improve the participation of childhood survivors in lifelong term follow-up care.

Comprehensive Clinical Evaluation

Independent of the setting in which it occurs, the clinical evaluation of the childhood cancer survivor should include a comprehensive treatment summary, thorough



Late Effects and the Childhood Cancer Care Continuum
Elements of care
Childhood Cancer Diagnosis
TRANSITION
Completion of Planned Therapy
TRANSITION
Pediatric Survivorship
TRANSITION
Adult Survivorship
Clinical:
• Consideration of late effects at diagnosis
- Fertility preservation
- Cardioprotection
- Bladder protectants
- Modification of radiation dose/field
- Chemotherapy total dose
• Monitoring on-therapy for late effects
- Audiography
- Echocardiography
- Other organ function
Clinical:
• Surveillance for recurrence
• Re-immunization
• Monitor growth and physical development
• Assess neurocognitive function
• Assess psychosocial function
• Monitor early organ toxicity
• Pediatric subspecialist referral
Clinical:
• Monitor organ toxicity
• Monitor growth and physical development
• Screening for SMN
• Assess neurocognitive function
• Assess psychosocial function
• Update family cancer history
• Pediatric subspecialist referral
• Surveillance for recurrence
Clinical:
• Monitor organ toxicity
• Screening for SMN
• Other cancer screening
• Assess psychosocial function
• Update family cancer history
• Adult subspecialist referral
• Surveillance recurrence
Education:
• Acute toxicity
• Potential late effects
Education:
• Treatment summary care plan
• Recurrence risk
• Introduce late effects risk
• Re-establish primary care
Education:
• Late effects risk
• Modifiable risk factors
• Healthy lifestyle
• Recurrence risk
• Update care plan
• Preparation for transition to adult care, begin age 12–14 yrs
Education:
• Late effects risk
• Modifiable risk factors
• Healthy lifestyle
• Recurrence risk
• Update care plan
• Transfer to adult providers

Figure 72-6 Late effects and the childhood cancer care continuum.

physical examination, and a care plan that includes recommendations for diagnostic or screening tests as indicated. The results of the evaluation should be summarized, documented, and communicated to the survivor and all health care providers participating in the survivor's care.

Treatment Summary

Information about prior diagnosis and treatment exposures is necessary for a health care provider to begin a comprehensive childhood cancer survivor's evaluation. This critical information is likely contained in a pediatric oncology "treatment summary." Details about diagnosis that are necessary for the survivor follow-up evaluation include age at diagnosis, presenting symptoms, results of diagnostic and staging evaluation, and pathology. Specifics of radiation therapy (field and dose); chemotherapy (specific agents and cumulative doses); surgeries (splenectomy, organ resections, and biopsies); and blood transfusions are all important component of a survivor's treatment history that contribute to the assessment of future health risks. Information about any required modifications in treatment, major acute complications of therapy, and ongoing treatment-related issues, such as chronic GVHD, should be available at the time of evaluation. For a provider not familiar with a survivor's prior therapy, a treatment summary can usually be obtained from the treating institution. A sample treatment summary template is provided in Figure 72-7. A summary of late effects associated with curative treatments for the most common childhood cancer diagnoses is presented in Table 72-4.

Medical History and Physical Examination

As in all medical assessments, obtaining and documenting a history of current and past medical problems is important to the childhood cancer survivor evaluation. Past medical history, including birth history, surgeries, and medical conditions that preceded the cancer diagnosis, may be pertinent. For older survivors, menstrual history, reproductive history, and obstetric history all contribute important information to the follow-up evaluation. Information about current medications and chronic medical conditions should also be obtained. Survivors should specifically be asked about any late effects diagnosed or treated to date, including subsequent cancers.

Figure 72-8 Late effects associated with common treatments for childhood cancer by organ systems. *CAD,* Coronary artery disease; *GI,* gastrointestinal; *TBI,* total-body irradiation; *VHD,* valvular heart disease.

Family history of chronic diseases, mental illness, and family cancer history are also an important part of the comprehensive survivor evaluation. Cancer diagnosed in first-degree relatives (parents, offspring, siblings) in a pattern suggestive of a hereditary cancer predisposition syndrome should be noted and appropriate referrals to cancer geneticists considered (see Box 72-2). A family history that includes other children with cancer raises particular concerns about hereditary cancer syndromes, as does a family history of genetic syndromes associated with cancer predisposition. A survivor's family history of common chronic diseases should be noted, with special attention to conditions for which the survivor may have treatment-related risk factors, such as heart disease, osteoporosis, or depression. Family history should be updated and reassessed at each subsequent evaluation.

All survivors should be asked about educational attainment and special education services or needs. For older survivors, employment history and insurance status are also critical to determining health care needs. Health behaviors including exercise, diet, sleep, tobacco use, alcohol use, and nonprescription drug use are also important aspects of the follow-up assessment. To further evaluate a survivor's emotional and physical needs not addressed in a medical history, survivors should be asked about their relationships with family and peers, sexual activity, and current living arrangements.

A comprehensive childhood cancer survivor's evaluation also includes a review of current and recent symptoms. This review of symptoms should include special consideration of symptoms known to be associated with specific late effects. Symptoms should be evaluated in light of the increased prior probability of significant morbidity compared with similar-aged patients. For example, a complaint of chronic headaches or sinus problems in a patient with a history of head and neck irradiation should be evaluated in light of the risk for radiogenic tumors; a young patient with dyspnea or chest pain might undergo a cardiac evaluation with a lower threshold than a patient who was not exposed to cardiotoxic therapies as a child.

A thorough physical examination including a skin examination and neurologic examination are also part of a childhood cancer survivor's routine evaluation. Radiation fields in particular should be examined carefully for any skin changes, masses, or lesions. A careful thyroid examination is indicated, in particular for patients who received radiation to the head, neck, chest or upper spine. Head, trunk, and limbs should be examined for growth disturbances related to surgery or irradiation, such as limb-length discrepancies, spinal deformity, and facial bone deformity. Major organ toxicity associated with specific chemotherapy agents and radiation fields commonly used to treat pediatric cancers is illustrated in Figure 72-8. Transplant survivors should be examined for signs of chronic GVHD.

Diagnostic and Screening Tests

The health care provider evaluating the childhood cancer survivor should arrange for diagnostic or screening tests and subspecialty consultations based on the survivor's treatment risks, symptoms, or other findings. The provider should recommend surveillance studies assessing primary disease recurrence if indicated; studies to assess organ function in any organs potentially affected by cancer therapy; and specialist consultation to evaluate findings or potential health risks. Depending on exposures, age, and gender, screening studies to assess for second cancers such as mammography or colonoscopy should be considered. Clinical guidelines developed by the Children's Oncology Group are available to help direct clinicians in the evaluation of survivors of childhood, adolescent, and young adult cancer.[89] These risk-based, treatment-related guidelines are intended to provide screening recommendations for late effects commonly observed in survivors.

Assessment and Follow-Up Plan

A childhood cancer survivor's risk for each late effect should be interpreted in light of his or her treatment history, past medical history, family history, symptoms, and physical examination. All findings and test results from the comprehensive survivor evaluation should be summarized in a survivorship care plan, and recommendations and plans for follow-up should be documented and communicated to the patient and all providers involved in the patient's care. Acknowledging the potential complexity of the survivorship care plan, the provider should prioritize the follow-up recommendations for the survivor and family and emphasize that this advice is limited by our current knowledge of late effects and based on future probabilities.

In summary, the successful follow-up care for the childhood cancer survivor depends on thorough evaluation with attention to possible late effects and effective communication with patient, family, and other providers involved in ongoing care.

FUTURE DIRECTIONS

Advances in the treatment of childhood cancer have resulted in growing numbers of survivors. Epidemiologic studies show that survivors of childhood cancer are likely to experience adverse health-related consequences of their treatment, and the potential to develop late effects appears to be lifelong. Although remarkable progress has been made in describing the late effects experienced by childhood cancer survivors and their associated risk factors, future research is needed to continue to decrease incidence and morbidity and to improve the quality of life for current and future survivors. In response, survivorship research is focused on three main areas: changes in primary cancer therapy that are focused on decreasing incidence of late toxicity; improvements in care to decrease the incidence or severity of particular late effects; and changes in the health care systems to ensure that all survivors have access to best practices to detect and manage late effects.

Current treatment protocols for childhood cancer are designed to minimize late effects without compromising survival. The strategies that have been investigated or are under investigation include eliminating or reducing exposures to specific chemotherapies with known late toxicities, such as anthracyclines and alkylating agents, developing chemoprotectant agents, reducing radiation dose and field, and delaying radiation therapy for very young children.[445-451] Studies to quantify the efficacy of these strategies to obviate late effects while maintaining survival are forthcoming. Current strategies for primary treatment of standard-risk acute lymphoblastic leukemia, localized Hodgkin lymphoma, Wilms tumor, and neuroblastoma designed to reduce late effects have resulted in excellent outcomes, with low incidence of both recurrence and treatment-related late effects, to date.[180,448,451,452]

Another strategy to reduce late morbidity in childhood cancer survivors is the identification of individuals with heightened susceptibility for specific treatment-associated late effects. One potential method of identification is genetic polymorphism testing, which identifies individuals with a genotype that is known to increase susceptibility to treatment-associated toxicity, such as second cancers, obesity, and cardiac disease.[128,453-455] Testing could be done before cancer treatment and the results used to modify treatment plans to account for an individual's genetic susceptibility for late effects. For example, lower-dose radiation therapy might be indicated for an individual identified by genetic polymorphism testing as having a genotype associated with irradiation-induced second cancers. Similarly, genetic polymorphism testing could be done decades after therapy to identify survivors at risk for late effects, which would inform screening recommendations and eligibility for preventive interventions.

Health services research focused on understanding cancer survivor care and studying improvements in care is ongoing. As the current population of childhood cancer survivors ages, health care delivery to this group will become more complex and will include integration of treatment-related risks and adult-onset morbidity. Optimal and innovative methods of patient (and health care provider) education that achieve this integration will need to be elucidated and disseminated to ensure the best possible quality of life for survivors of childhood cancer.

The care of the child diagnosed with cancer does not end with the completion of therapy. Consequently, pediatric oncology providers need to have a working knowledge of the potential late effects of curative therapy for childhood cancer and are responsible to communicate information about late effects to survivors, their families, and other health care providers involved in the care of childhood cancer survivor. Pediatric survivorship research has made significant contributions to advance our understanding of long-term treatment–associated morbidities, and current therapeutic protocols are designed with the intention of minimizing known late effects. However, despite progress, childhood cancer survivors remain vulnerable to many long-term treatment related morbidities. Ongoing efforts in research and clinical care for childhood cancer survivors must be directed toward improving and extending follow-up care, at developing interventions for individuals identified as being at risk for specific late effects, and at optimizing management of late effects with the ultimate aim of improving quality of life for all current and future childhood cancer survivors.

KEY REFERENCES

10. Li FP, Cassady JR, Jaffe N: Risk of second tumors in survivors of childhood cancer. *Cancer* 35:1230–1235, 1975.

This study is one of the first descriptions of the association between treatment of childhood cancer and the development of second primary malignancies decades after treatment. In this single-institution study researchers reported the 20-year cumulative probability of a second cancer (12% SE 4%). They describe the association between therapeutic radiation and second cancers as well as suggest that host susceptibility may be an etiologic factor.

21. Armstrong GT, Liu Q, Yasui Y, et al: Late mortality among 5-year survivors of childhood cancer: a summary from the Childhood Cancer Survivor Study. *J Clin Oncol* 27:2328–2338, 2009.

This is a comprehensive summary of the CCSS mortality data based on a cohort of 20,483 childhood cancer survivors, representing 337,334 person-years of observation, linked to the National Death Index and death certificates. Overall cumulative mortality, patterns of late death over time, cause-specific mortality, and specific treatment-related risk factors for late mortality are described.

29. Robison LL, Mertens AC, Boice JD, et al: Study design and cohort characteristics of the Childhood Cancer Survivor Study: a multi-institutional collaborative project. *Med Pediatr Oncol* 38:229–239, 2002.

The CCSS is a consortium of 25 North American institutions representing one of the largest and most extensively characterized cohorts of childhood and adolescent cancer survivors (diagnosed prior to age 21 years with selected cancer diagnoses, diagnoses between 1970-1986, and survival for at least 5 years). This reference is a description of the methodology used to develop the CCSS, which serves as a resource for addressing risk for second malignancies, endocrine and reproductive outcomes, cardiopulmonary complications, and psychosocial implications among childhood cancer survivors.

33. Reulen RC, Frobisher C, Winter DL, et al: Long-term risks of subsequent primary neoplasms among survivors of childhood cancer. *JAMA* 305:2311–2319, 2011.

The British Childhood Cancer Survivor Study is a population-based cohort of 17,981 5-year survivors of childhood cancer diagnosed with cancer when younger than 15 years between 1940 and 1991 in Great Britain, followed up through December 2006. In this study the cohort is used to investigate the long-term risks of subsequent primary neoplasms in survivors of childhood cancer, to identify the cancer types that contribute most to long-term excess risk, and to identify subgroups of survivors at substantially increased risk for particular subsequent primary neoplasms.

36. van der Pal HJ, van Dalen EC, van Delden E, et al: High risk of symptomatic cardiac events in childhood cancer survivors. *J Clin Oncol* 30:1429–1437, 2012.

This cohort study assessing the long-term risk for clinically validated, symptomatic cardiac events in 5-year survivors of childhood cancer demonstrated that higher cumulative anthracycline dose or higher cumulative radiation dose was associated with higher risk ratio for cardiac events. Survivors with both anthracycline and cardiac irradiation exposures had the highest cumulative incidence of cardiac events, with nearly one in eight survivors treated with both exposures developing a serious cardiac event.

46. Oeffinger KC, Mertens AC, Sklar CA, et al: Chronic health conditions in adult survivors of childhood cancer. *N Engl J Med* 355:1572–1582, 2006.

This report from the Childhood Cancer Survivor Study details chronic health conditions in adult survivors of childhood cancer. The relative risk for a severe or life-threatening chronic condition in survivors when compared with siblings was 8.2 (95% CI, 6.9-9.7).

47. Hudson MM, Ness KK, Gurney JG, et al: Clinical ascertainment of health outcomes among adults treated for childhood cancer. *JAMA* 309:2371–2381, 2013.

This report of clinically ascertained health outcomes among adult survivors of childhood cancer from the St. Jude Lifetime Cohort Study presents the prevalence and adverse health outcomes of 1713 adult survivors of childhood cancer. Survivors underwent comprehensive, risk-based clinical assessment. The cumulative prevalence of a chronic condition was estimated as 95.5% (95% CI, 94.8%-98.6%) and the cumulative prevalence of a severe or life-threatening/disabling condition was estimated as 80.5% (95% CI, 73.0%-86.6%) by age 45 years.

51. Friedman DL, Whitton J, Leisenring W, et al: Subsequent neoplasms in 5-year survivors of childhood cancer: the Childhood Cancer Survivor Study. *J Natl Cancer Inst* 102:1083–1095, 2010.

In this study, the CCSS cohort was used to update the incidence of and risk for subsequent neoplasms occurring 5 years or more after the childhood cancer diagnosis from 14,359 5-year survivors in the CCSS who were at a median age of 30 years (range, 5 to 56 years) at follow-up. Cumulative incidence of subsequent neoplasm at 30 years, standardized incidence ratios, excess absolute risks for invasive second malignant neoplasms, and relative risks for subsequent neoplasms are presented. The study confirms that as childhood cancer survivors progress through adulthood, risk for subsequent neoplasms increases and there is no evidence of risk reduction with increasing duration of follow-up.

55. Garber JE, Offit K: Hereditary cancer predisposition syndromes. *J Clin Oncol* 23:276–292, 2005.

This review highlights the most common hereditary cancer syndromes and a number of rare syndromes in which particular progress has been made. The prevalence, penetrance, tumor spectrum, and underlying genetic defects are discussed and then summarized in a table in which a comprehensive listing of known hereditary cancer syndromes is provided.

61. Kenney LB, Yasui Y, Inskip PD, et al: Breast cancer after childhood cancer: a report from the Childhood Cancer Survivor Study. *Ann Intern Med* 141:590–597, 2004.

This study identifies risk factors for secondary breast cancer beyond chest radiation therapy among female survivors of childhood cancer. In the CCSS cohort, breast cancer risk for female survivors was independently associated with prior chest radiation therapy, primary diagnosis of bone and soft tissue sarcoma, family history of breast cancer, and history of thyroid disease. In addition, prior pelvic radiation was found to reduce breast cancer risk.

67. Bassal M, Mertens AC, Taylor L, et al: Risk of selected subsequent carcinomas in survivors of childhood cancer: a report from the Childhood Cancer Survivor Study. *J Clin Oncol* 24:476–483, 2006.

This study describes childhood cancer survivors' risk for subsequent carcinomas other than the three most common (breast, thyroid, and skin) using standardized incidence ratios calculated from the CCSS cohort and Surveillance, Epidemiology, and End Results program data. Young survivors of childhood cancers were found to be at increased risk for developing subsequent carcinomas typically associated with older adulthood, including those of the genitourinary system, head and neck area, and gastrointestinal tract.

73. Henderson TO, Oeffinger KC, Whitton J, et al: Secondary gastrointestinal cancer in childhood cancer survivors: a cohort study. *Ann Intern Med* 156:757–766, 2012.

This analysis from the CCSS characterizes risk factors for childhood cancer survivors to develop secondary gastrointestinal cancer. Results show the greatest risk for subsequent gastrointestinal cancer is prior abdominal radiation; however, high-dose procarbazine and platinum chemotherapy were also found to independently increase the risk.

75. Travis LB, Hill DA, Dores GM, et al: Breast cancer following radiotherapy and chemotherapy among young women with Hodgkin disease. *JAMA* 290:465–475, 2003.

This matched case-control study of 3817 female Hodgkin lymphoma survivors provides a detailed analysis of the relative risk for secondary breast cancer associated with both radiation dose delivered to site of breast cancer or to ovaries and with the cumulative dose of alkylating agent chemotherapy. Results of this study support the importance of hormonal stimulation for the development of radiation-induced breast cancer, as evidenced by the reduced risk associated with ovarian damage from alkylating agents or ovarian radiation.

89. Children's Oncology Group: *Long-Term follow-up guidelines for survivors of childhood, adolescent and young adult cancers, version 3.0*, Arcadia, CA, 2008, Children's Oncology Group. Accessed at: http://www.survivorshipguidelines.org/.

These Children's Oncology Group Long-Term Follow-Up Guidelines for Survivors of Childhood, Adolescent, and Young Adult Cancer (COG-LTFU Guidelines) are evidence-based recommendations for screening and management of late effects of therapeutic exposures. They are updated by a multidisciplinary panel based on current literature review and expert consensus.

93. Sklar CA, Whitton J, Mertens A, et al: Abnormalities of the thyroid in survivors of Hodgkin's disease: data from the Childhood Cancer Survivor Study. *J Clin Endocrinol Metab* 85:3227–3232, 2000.

Treatment of childhood cancer is associated with a variety of thyroid abnormalities. This early analysis from the CCSS comparing Hodgkin lymphoma survivors to sibling controls describes relative risks for hypothyroidism, hyperthyroidism, thyroid nodules, and thyroid cancer. It also characterizes the interaction between various patient and treatment variables. Female sex, radiation dose, and younger age at diagnosis were found to be independent risk factors for thyroid disease.

110. Henderson TO, Whitton J, Stovall M, et al: Secondary sarcomas in childhood cancer survivors: a report from the Childhood Cancer Survivor Study. *J Natl Cancer Inst* 99:300–308, 2007.

Childhood cancer survivors are at increased risk for secondary sarcomas. This analysis from the CCSS determined the incidence of secondary sarcomas and examined factors associated with the risk for developing secondary sarcomas. In a multivariable model, increased risk for secondary sarcoma was associated with radiation therapy, with a primary diagnosis of sarcoma, and with treatment with anthracyclines.

126. Taylor AJ, Little MP, Winter DL, et al: Population-based risks of CNS tumors in survivors of childhood cancer: the British Childhood Cancer Survivor Study. *J Clin Oncol* 28:5287–5293, 2010.

A large cohort study of CNS tumors in survivors of childhood cancer from the British Cancer Survivor Study linked to national population–based cancer registries investigated treatment-related risk factors. Investigators found that the risk of secondary meningioma increases linearly and independently with increased dose of radiation to meningeal tissue and also with increased dose of intrathecal methotrexate. The risk for secondary glioma/primitive neuroectodermal tumors also increased linearly with dose of therapeutic radiation.

130. Nottage K, McFarlane J, Krasin MJ, et al: Secondary colorectal carcinoma after childhood cancer. *J Clin Oncol* 30:2552–2558, 2012.

In this nested case-control study of 13,048 childhood cancer survivors from St Jude Children's Research Hospital, the long-term risk for secondary adenocarcinoma of the colon or rectum is reported to be 10-fold greater in survivors compared with the age-matched general population. Matched-pairs analyses found that radiation and alkylator exposure are associated with increased risk for secondary colorectal carcinoma and that the risk is proportional to dose and volume of radiation received. These data support the recommendation for early colon cancer screening for survivors receiving high-risk exposures.

152. Lipshultz SE, Adams MJ, Colan SD, et al: Long-term cardiovascular toxicity in children, adolescents, and young adults who receive cancer therapy: pathophysiology, course, monitoring, management, prevention, and research directions: a scientific statement from the American Heart Association. *Circulation* 128:1927–1995, 2013.

This detailed report provides a comprehensive review of long-term cardiovascular toxicity associated with treatment of malignancy in childhood, adolescence, and young adulthood.

210. Bowers DC, Liu Y, Leisenring W, et al: Late-occurring stroke among long-term survivors of childhood leukemia and brain tumors: a report from the Childhood Cancer Survivor Study. *J Clin Oncol* 24:5277–5282, 2006.

This report assesses the incidence of and risk factors for late-occurring stroke among survivors of childhood leukemia and brain tumors. The relative risk for stroke for leukemia survivors was 6.4 (95% CI, 3.0-13.8) and for brain tumor survivors it was 29.0 (95% CI, 13.8-60.6) compared with a sibling comparison group.

214. Armstrong GT, Oeffinger KC, Chen Y, et al: Modifiable risk factors and major cardiac events among adult survivors of childhood cancer. *J Clin Oncol* 31:3673–3680, 2013.

In this assessment of adult survivors of childhood cancer from the CCSS, two or more cardiovascular risk factors were reported by 10.3% of survivors. In this report, acquisition of modifiable cardiovascular risk factors, particularly hypertension, increased the risk for a severe, life-threatening, and fatal cardiac event, reinforcing the importance of early diagnosis and careful management of modifiable cardiovascular risk factors in survivors.

219. Mertens AC, Yasui Y, Liu Y, et al: Pulmonary complications in survivors of childhood and adolescent cancer: a report from the Childhood Cancer Survivor Study. *Cancer* 95:2431–2441, 2002.

In this report from the CCSS, survivors of childhood cancer were found to have a significantly increased risk for pulmonary complications compared with siblings, including an increased risk of lung fibrosis, recurrent pneumonia, and use of supplemental oxygen.

223. Cohen LE: Endocrine late effects of cancer treatment. *Endocrinol Metab Clin North Am* 34:769–789, xi, 2005.

This review article describes the endocrinopathies that are associated with the treatment of childhood cancers, specifically hypothalamic-pituitary, thyroid, and gonadal dysfunction, as well as osteopenia-osteoporosis and obesity. The article also addresses the risk factors for endocrine complications, including the underlying disease, treatment with cytotoxic agents, and radiation therapy.

249. Kadan-Lottick NS, Dinu I, Wasilewski-Masker K, et al: Osteonecrosis in adult survivors of childhood cancer: a report from the Childhood Cancer Survivor Study. *J Clin Oncol* 26:3038–3045, 2008.

In the CCSS cohort, the 20-year cumulative incidence of osteonecrosis was 0.43%, with survivors 5.6 times more likely to have reported osteonecrosis compared with siblings. The risk for osteonecrosis was greatest among survivors of allogeneic stem cell transplant for underlying diagnoses of leukemia in survivors of acute lymphoblastic leukemia, acute myelogenous leukemia, and bone sarcoma.

299. Krull KR, Brinkman TM, Li C, et al: Neurocognitive outcomes decades after treatment for childhood acute lymphoblastic leukemia: a report from the St. Jude Lifetime Cohort Study. *J Clin Oncol* 31:4407–4415, 2013.

    In this report, adult survivors of childhood acute lymphoblastic leukemia were found to have significant and pervasive neurocognitive impairment.

341. Metzger ML, Meacham LR, Patterson B, et al: Female reproductive health after childhood, adolescent, and young adult cancers: guidelines for the assessment and management of female reproductive complications. *J Clin Oncol* 31:1239–1247, 2013.

    This is a comprehensive review of the literature that informed the COG-LTFU guidelines task force recommendations for the assessment and management of female reproductive complications after treatment of childhood, adolescent, and young adult cancers. Topics include all aspects of female reproductive and sexual health, including hypogonadism, precocious puberty, and reduced fertility. Also reviewed is current knowledge in other areas relevant to the reproductive health of female survivors of childhood cancer, including investigational fertility preservation, interventions for infertility, and sexual function.

349. Kenney LB, Cohen LE, Shnorhavorian M, et al: Male reproductive health after childhood, adolescent, and young adult cancers: a report from the Children's Oncology Group. *J Clin Oncol* 30:3408–3416, 2012.

    This is a comprehensive review of the literature that informed the COG-LTFU guidelines task force recommendations for the assessment and management of male reproductive complications after treatment of childhood, adolescent, and young adult cancers. This review presents an overview of male reproductive complications, including hypoandrogenism, precocious puberty, reduced fertility, and sexual dysfunction. Risk factors, clinical assessment, and interventions for each of the treatment-associated complications, as put forth in the guidelines, are discussed.

363. Green DM, Whitton JA, Stovall M, et al: Pregnancy outcome of female survivors of childhood cancer: a report from the Childhood Cancer Survivor Study. *Am J Obstet Gynecol* 187:1070–1080, 2002.

    This study reviews self-reported pregnancy outcome among female participants in the Childhood Cancer Survivor Study to determine the effect of prior treatment with radiation therapy or chemotherapy for cancer diagnosed during childhood or adolescence on pregnancy loss, live births, and birth weight. This large study did not identify adverse pregnancy outcomes for female survivors treated with most chemotherapeutic agents; however, the offspring of women who received pelvic irradiation are at risk for low-birth-weight infants.

407. Goldsby R, Chen Y, Raber S, et al: Survivors of childhood cancer have increased risk of gastrointestinal complications later in life. *Gastroenterology* 140:1464–1471, 2011.

    This study from the Childhood Cancer Survivor Study cohort evaluates the incidence of long-term gastrointestinal disease for childhood cancer survivors and identifies treatment-related risk factors. Compared with siblings, survivors had increased risk for late onset complications of the upper gastrointestinal tract, liver, and lower gastrointestinal tract. Older age at diagnosis, intensified therapy, abdominal radiation, and abdominal surgery increased the risk for certain gastrointestinal complications.

419. Kaste SC, Goodman P, Leisenring W, et al: Impact of radiation and chemotherapy on risk of dental abnormalities: a report from the Childhood Cancer Survivor Study. *Cancer* 115:5817–5827, 2009.

    In this report from the CCSS, survivors when compared with siblings, were more likely to report microdontia, hypodontia, root abnormalities, abnormal enamel, teeth loss, severe gingivitis, and xerostomia.

422. Recklitis CJ, Diller LR, Li X, et al: Suicide ideation in adult survivors of childhood cancer: a report from the Childhood Cancer Survivor Study. *J Clin Oncol* 28:655–661, 2010.

    In this report from the CCSS, adult survivors of childhood cancer were at increased risk for suicidal ideation compared with the sibling control cohort. In survivors, suicidal ideation was associated with a primary diagnosis of central nervous system malignancy, depression, and poor current physical health.

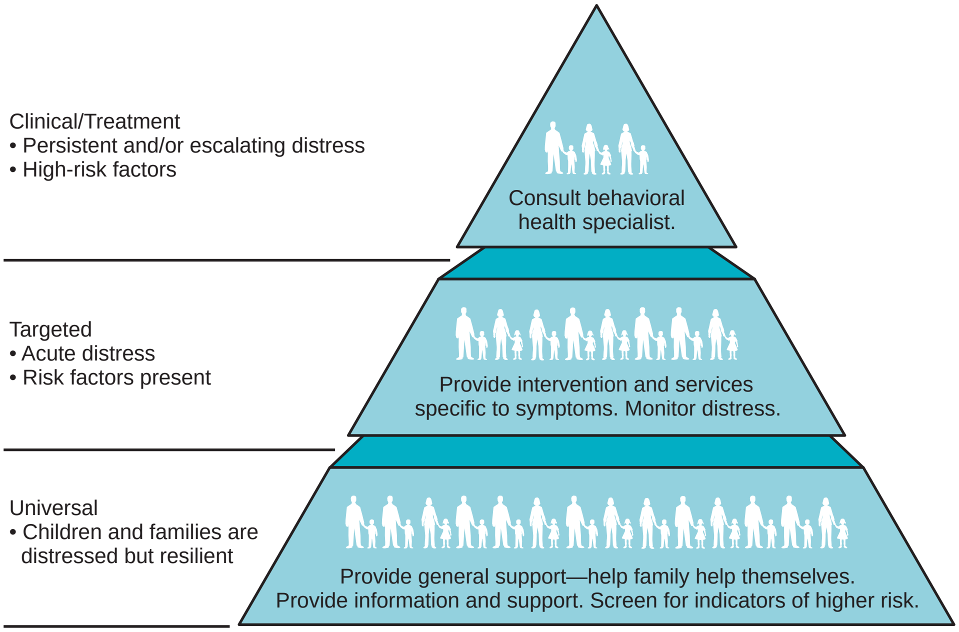
SPECIAL POPULATIONS
Adolescents
Neurooncology
Hematopoietic Stem Cell Transplant

The diagnosis and treatment of cancer represents a major challenge for the family and the individual child. For most families, coping with a child's cancer will be the most stressful and difficult experience they will face. Although the majority of families will make an adequate adjustment,[1-4] coping with the diagnosis and the subsequent challenges of treatment is a difficult and demanding process.[5-9] In this chapter we will address the emotional and psychosocial needs of children and their families while the child receives a diagnosis of cancer and undergoes therapy, and describe some resources and interventions that may be useful. This chapter is intended primarily for oncologists, nurse practitioners, and other medical professionals who are seeking to understand and attend to the psychosocial needs of children with cancer. In each section we highlight the issues facing the child and family and suggest supportive strategies or interventions that may be helpful. A description of the psychosocial clinician's role is included in certain sections so that oncology providers can better understand and collaborate with psychosocial clinicians, but readers looking for a detailed description of psychosocial assessment and treatment techniques will need to look beyond this chapter to more comprehensive treatments of the subject.[4,10,11,12,13] Given the great variability in oncology diagnoses and treatments, as well as individual differences in children and families, we will focus on the issues that are most common in this population. Beginning with the crisis of diagnosis and proceeding chronologically through the treatment period to the end of therapy, we will address the issues that are expected to arise for most families.

CONCEPTUAL MODELS GUIDING THE PSYCHOSOCIAL CARE OF CHILDREN AND FAMILIES

In approaching the topic of psychosocial care for the child and family, we have adopted a conceptual model developed by Anne Kazak[14] that illustrates the different levels of need seen in families of children with cancer (Fig. 73-1). In this model, adapted from the preventative mental health model,[14] Kazak represents the distribution of families along the continuum of needs in the form of a pyramid, with the least acute needs at the bottom and



Clinical/Treatment
• Persistent and/or escalating distress
• High-risk factors
Consult behavioral health specialist.
Targeted
• Acute distress
• Risk factors present
Provide intervention and services specific to symptoms. Monitor distress.
Universal
• Children and families are distressed but resilient
Provide general support—help family help themselves.
Provide information and support. Screen for indicators of higher risk.

Figure 73-1 Pediatric psychosocial preventative health model. *(From Kazak AE: Pediatric psychosocial preventative health model [PPPHM]: research, practice, and collaboration in pediatric family systems medicine.* Fam Syst Health *24:381–395, 2006.)*

the most acute needs at the top. The largest section of the pyramid at the bottom represents the majority of patients and families who have expected levels of distress but generally have adequate resources and may benefit from information and psychosocial support. Moving up the pyramid, the second largest group of families represented have more significant needs according to Kazak, either because of existing risk factors or the presence of more acute distress. Finally, at the top of the pyramid is the smallest group of families, whose level of distress is in the clinical range and for whom some significant behavioral or psychiatric intervention is required. This chapter focuses on describing the needs of the largest group of families with “universal” or expected needs and discussing the support strategies and interventions that can be helpful for them. In addition we address some of the special issues that are likely to be seen in the “targeted” group of families such as noncompliance or marital conflicts that are not typical but that the treatment team should be aware of and be prepared to address. In the less common situations in which patients or parents require significant mental health interventions, referrals to specialists are necessary; these situations will be discussed briefly at the end of this chapter.

The ecological and developmental perspectives are also essential for understanding the experience of the child and family going through cancer therapy. Urie Bronfenbrenner (1917-2005) created the modern concept of the ecology of human development.[15] In his model no one factor operates in isolation, and the biopsychosocial model is considered within a developmental context. At the core of the model, the child has genetic and environmental influences on emotions, cognition, and behavior. In addition the child’s own responses to the environment not only influence his or her emotions, thoughts, and behaviors but in turn influence the microenvironment.[16,17] For example a child who responds to new situations with aggression or fear will elicit different responses from medical providers than will a child who responds with curiosity, and in that way the child shapes the environment to which he or she was initially reacting. At the next level of the model, the family system is a powerful factor that directly affects the child and shapes many of the child’s interactions with the environment. Family factors including family composition, parental emotional states, socioeconomic status, and other family stressors will influence the child’s experience of illness.[18-22] For example parental depression might reduce the extent of nurturing and support provided to a child with cancer. Recommendations for family-centered care as the primary model of care delivery for children are supported by this aspect of the model (Fig. 73-2).[20]

Finally, at the broadest level, racial, ethnic, community, and cultural factors can have an impact on the entire family/child system (Fig. 73-3).[23]

From a developmental perspective, children go through five recognizable stages of development from the newborn period until adulthood. These stages typically are thought of as infant, toddler, preschool, school age, and adolescence. Different developmental tasks are associated with each stage, and the needs for information, support, and care will vary in relation to the developmental stage of the child. A review of how to communicate with sick children during different developmental stages is provided by Rushforth.[24] Pediatric health care providers are accustomed to tailoring their general approach to patients and families according to the child’s developmental stage and will draw on these skills and experience

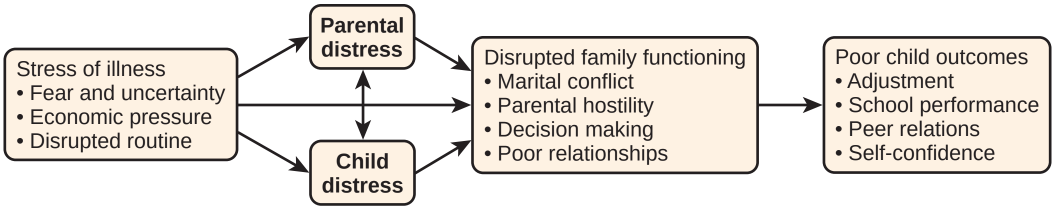


Figure 73-2 Family stress model. *(Modified from Conger KJ, Rueter MA, Conger RD: The role of economic pressure in the lives of parents and their adolescents: the family stress model. In Crockett LJ, Silbereisen RJ, editors:* Negotiating adolescence in times of social change. *Cambridge, England, 2000, Cambridge University Press, p. 201–233.)*

when working with children who have cancer. For example infants generally need a significant degree of parental soothing and physical contact, as do toddlers, yet toddlers need room for explanation and consistency in the environment. Preschool-aged children can understand simple information that can help reduce fears of the unknown. School-aged children need to have opportunities for peer interaction, as well as clear communication. Adolescents have a need for the development of autonomy and identity formation. When little room for individual choice is perceived by the adolescent, the drive for independence can lead to maladaptive coping, such as nonadherence to medications or refusals to come to the clinic or undergo medical procedures. Adolescents with cancer by necessity become more dependent upon their parents for physical and emotional needs and may have self-image issues related to weight loss or baldness, because during this developmental period perceptions of peer acceptance are important and sexuality develops as well.[25,26] The specific needs of the adolescent patient are discussed in a separate section.

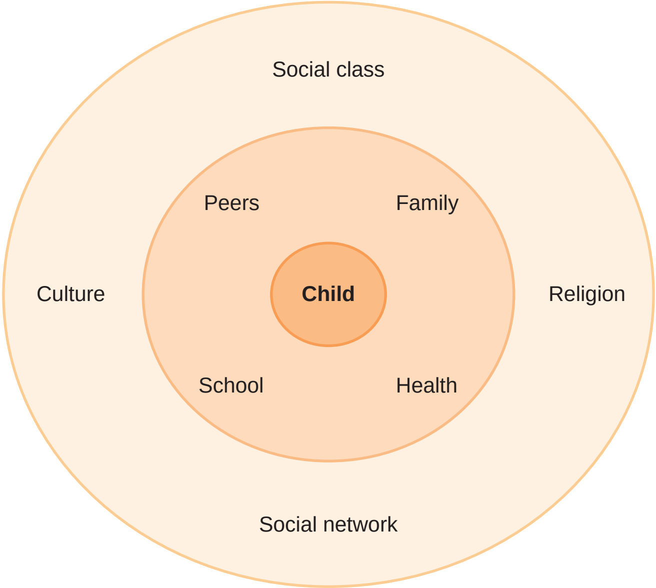

Figure 73-3 Child health from an ecological perspective. *(Modified from Kazak AE: Pediatric psychosocial preventative health model [PPPHM]: research, practice, and collaboration in pediatric family systems medicine.* Fam Syst Health *24:381–395, 2006.)*

PROFESSIONAL ROLES AND A TEAM APPROACH TO PSYCHOSOCIAL CARE

No single individual is able to provide for all the psychosocial needs of the child and family undergoing cancer therapy. In many pediatric oncology settings a team approach[27-30] is used, with the team composed of both medical and psychosocial care providers. The composition of the medical members of the team vary from setting to setting, but the team generally includes an attending oncologist, a surgeon, and a radiation oncologist (if these treatment modalities are indicated), as well as other oncology care providers such as an oncology fellow, a nurse practitioner or physician's assistant, and an oncology nurse. Psychosocial members of the team may include a resource specialist, social worker, psychologist, child life specialist, or psychiatrist. Variation in the professions included in the psychosocial support team in a particular treatment setting generally has more to do with local culture and tradition than with the specific training or skills of a particular profession. Although each psychosocial discipline has its particular focus or specialized skill set[31-38] (e.g., prescriptive authority or psychological testing) in working with children who have cancer and their families, considerable overlap between their roles is likely.

Psychosocial professionals have several important roles on the care team. The primary role may be as a consultant to other members of the team, including the patient and the family.[39-42] Because all team members will be interacting and providing some level of information and support, they will need to attend to psychosocial concerns, and developing a consistent approach to support of the family is essential.[43] As a consultant, the psychosocial team members should conduct a preliminary assessment of the child and family to understand their history, preferred ways of coping, important supports, and potential sources of vulnerability. Using this knowledge of the family, the psychosocial care provider may be able to help the other team members understand the family's individual needs and consider best approaches for supporting them. Similarly when the patient or family has questions and concerns that are not resolved in the course of routine care, the psychosocial care provider may help them work on solving the issue and think about how to help them raise their concerns with the medical team. The emphasis of these consultations is on improving communication between the family and the medical team, and in most instances these consultations focus on clarifying and correcting misunderstanding rather than resolving conflicts. In cases in which the family is very reluctant to address a concern with the medical team, or when a more significant conflict exists with the medical team, the psychosocial team member may be asked to play a more formal consultant role. Psychosocial team members also fulfill the role of direct service providers to patients and families, providing individual or family meetings to offer support to the parents, patient, or family, as well as education and preparation for surgery and other medical procedures. Support groups run by psychosocial and/or nursing staff in the inpatient or outpatient setting may be very helpful for meeting families' educational and emotional needs.[44-47] Finally, the psychosocial provider's role often includes consultation and liaison with outside agencies and community resources.[48-51] This aspect may include assisting families in accessing financial and insurance resources, contacting schools, tutors, and other child care agencies, and helping identify additional support services in the community, including referrals for psychotherapy when appropriate.

CRISIS OF A CANCER DIAGNOSIS

The cancer diagnosis and the events leading up to it are typically frightening, complex, and unfamiliar.[7,8,52] The diagnosis period, which can be thought of as beginning when the child first comes to medical attention until a clear diagnosis and treatment plan are made, is foremost a period of uncertainty. At some point in this period, parents are told cancer is possible or even likely, but it may take time before a definitive diagnosis is made. During this period their child's symptoms may persist and the child often must face painful diagnostic tests and procedures.

Until their child is diagnosed, most families have never thought about childhood cancer and don't know anyone who has had to face it. Whereas families facing common stressful life events can be guided by their prior experiences and the experience of their friends and family, the cancer diagnosis pushes them beyond the realm of ordinary experience. Not surprisingly parents are typically overwhelmed emotionally and cognitively while they try to understand their child's illness. In addition parents may describe feelings of unreality, "like this is not really real." Children's immediate reactions to illness depend largely on their age, their symptoms, and the medical procedures they have had to undergo. Except in cases of older adolescents, it is most often the parents who are most anxious to learn the diagnosis and are the first ones to be informed of the diagnosis of cancer.

Presenting the Diagnosis and Plan for Treatment: Day One Talk

The diagnostic period comes to a close when the treatment team has made a clear diagnosis of the child's cancer and communicates this diagnosis and related treatment plan to the patient and family. Often referred to as the "day one talk," this conversation with the family usually takes place in the form of a treatment conference between the family and several members of the care team, including physicians, nurses, and psychosocial care providers. The day one talk is a comprehensive discussion and usually the first to address the child's prognosis and specific treatment recommendations. For many families this meeting is a pivotal event in their lives, marking the real beginning of their child's cancer. Throughout the diagnostic phase most families maintain hope that the child does not in fact have cancer, so the day one talk is similar to other situations in which a physician must communicate bad news to the family. The literature on communicating bad news about a child's health[53-57] may be relevant, and recommendations from these noncancer settings may be instructive. Box 73-1 provides a summary of essential points for communicating the diagnosis.

Although the medical details discussed will vary from one family to the next, challenges in communicating diagnostic, prognostic, and treatment information are consistent across families and can be considered and planned for.[58-61] Planning is essential for a successful meeting with the family, and although there may be pressure from family or medical staff to have the conversation as soon as possible, some minimal amount of scheduling and organization will be required. A written protocol for communicating the diagnosis has been recommended,[60] with the expectation that this protocol will

Box 73-1 **Summary of Essential Points: Principles for Communicating the Diagnosis**

STRUCTURE—ORGANIZATION

- Establish an initial plan for communication.
- Communicate in a private and comfortable space where interruptions will be minimized.
- Communicate with the parents, child, and other family members, if desired. Nursing staff and psychosocial workers should also be included whenever possible.
- Hold a separate session with the child if he or she is not present for the initial communication.

CONTENT—INFORMATION TO DISCUSS

- Solicit questions from the parents and child, especially regarding their understanding of the present illness.
- Share information about the diagnosis, treatment, and the plan for cure and/or goals of treatment.
- Share information on lifestyle and psychosocial issues, particularly surrounding causation (e.g., the cancer is neither the child's nor family's fault).

PROCESS—PROCESS OF COMMUNICATION

- Communicate immediately at diagnosis and follow-up later.
- Communicate at a pace the family can follow, allowing the child's or family's emotional reaction to guide the flow of the conversation.
- Communicate in ways that are sensitive to cultural differences (e.g., for families who are not native English speakers, arrangements should be made for an interpreter).
- Encourage the entire family to talk together.

Modified from Krahn GL, Hallum A, Kime C: Are there good ways to give bad news? Pediatrics *91:578–582, 1993; Mack JW, Grier HE: The day one talk.* J Clin Oncol *22:563–566, 2004; and Masera G, Chesler MA, Jankovic M, et al: SIOP Working Committee on Psychosocial Issues in Pediatric Oncology: guidelines for communication of the diagnosis.* Med Pediatr Oncol *28:382–385, 1997.*

be tailored to meet the needs of the patient and family. Conducting the meeting in a private space while all participants are free from interruptions is very important, as is scheduling the meeting so that the important members of the family and care team can attend. Because families typically find the day one talk overwhelming[58,62-64] and may not remember many of the details discussed, some practitioners recommend providing written material or making a tape recording of the meeting for the parents to review subsequently.[63,65-68] Reassuring families that they are not expected to remember all of the details discussed can reduce their sense of information overload, as will making explicit the critical pieces of information they are being asked to focus on.

In addition to the oncologists directly caring for the patient, the day one talk should include nurses and psychosocial caregivers whenever possible.[69,70] The organization and roles of the medical center staff are often confusing to families, and taking time to introduce the different members of the team and describe their roles is essential. Both parents should attend, and they should be offered the opportunity to include other family members involved in the care of the child. Whether to include the child in all or part of this session or to arrange for a separate session for the child will depend largely on the age of the child and the parents' preference. Although a subsequent meeting with a smaller group consisting of parents and one or two medical professionals may be more appropriate for younger children,[71-73] including adolescents in the day one talk can help them develop trust in the medical team and invest in their own care.[58,74]

The principal goal of the meeting is to provide the family with an overview of the child's diagnosis, the treatment recommendations, and the prognosis. It is important to directly elicit questions the patient or family may have and to provide sufficient time to discuss their concerns. Mack and Grier[58] emphasize the opportunity to address the family's questions about what may have caused the child's cancer and particularly to correct misconceptions that may lead to a sense of blame or responsibility for the cancer. Communicating prognostic information to the family is critical because it is likely to have an impact on their understanding of the treatment recommendations,[75,76] but delivering this information can be difficult, especially when the prognosis is guarded or poor. How much to rely on a numeric presentation of this information is a question that frequently arises, and some evidence indicates that patients may misunderstand the information[77-79] if it is not carefully explained. Numeric information about risk, such as 5-year survival rates, should not be avoided altogether because many families want this information,[80] but care should be taken to ensure that parents receive the information in the way they find most useful and that they understand the information that is provided. Recommendations for treatment should be presented, beginning with a general overview of the modalities used and the timing and setting for treatments. The introduction of consent forms and discussion of known and likely adverse effects (short term and long term) should follow after the family understands the general outline of the treatment.

If a separate session for the child is held, the same general information about diagnosis, prognosis, and treatment plan should be covered. The information will need to be tailored to the developmental level and the particular concerns of the patient, such as the ability to return home and to school, to see friends, and to participate in sports or other activities.[74] Children should be told about specific expectable adverse effects such as hair loss, with an emphasis on concrete ways in which their appearance or activities may be affected. Older children and adolescents may be able to engage directly with the medical providers, but younger children may be more comfortable talking with their parents, who can elicit their questions and reinforce what medical providers communicate to the child directly. Most professionals will emphasize the importance of the children knowing the name of their disease and that it is cancer. Parents may initially shy away from this direct approach and particular words like "cancer," and they may need some preparation for how to talk with their child and what words to use. Understandably many parents feel protective toward their children and may wish to avoid using the words "cancer" or "leukemia." It is important to help parents understand that honesty, even about potentially frightening information, can decrease anxiety and be supportive for children in the long term because they can grow to trust that adults are not withholding information and that they need not fear unpleasant surprises. Similarly it is important to explain that the word "cancer" is commonly used with pediatric patients and that it is important for children not to feel that their condition is so frightening it cannot be named or spoken about. It can be helpful to share with parents that the climate of open communication with young patients comes from lessons learned in past treatment eras when communication was not open, which contributed to children's anxiety and fear about their disease. With this sort of preparation, most parents can begin to feel comfortable with open communication with the child. Parents from different cultural backgrounds,[73,81,82] or those who are unused to open discussions of illness, may not easily accept this openness and naming of the disease, and some careful negotiation and compromise may be required to reach an agreement of what words to use and topics to discuss with the patient. Over time families may become more comfortable being open with the patient themselves, while they meet other families and children whom they see are comfortable with this type of open discussion. In an elegant description of the day one talk in pediatric oncology, Mack and Grier[58] highlight the importance of forming an alliance between the family and the medical provider and the ways in which this alliance can affect adjustment to the diagnosis. In particular they emphasize the importance of listening closely, making an emotional connection with the family, and acknowledging the overwhelming impact of the diagnosis on every aspect of the family's life. Although they provide some very specific guidelines for the information that should be discussed, they conclude, "…listening and the openness of silence may be more important than the words themselves."[58]

Parents' Reactions to a Child's Diagnosis

Many factors can contribute to the overwhelming nature of the cancer diagnosis. The word "cancer" continues to have a significant social stigma,[83-88] as well as personal connotations. For many parents, their personal experiences with cancer may be limited to relatives who were diagnosed later in life and may not have survived long after diagnosis. Although it can be helpful to learn about these personal associations with cancer, it is very important to clearly correct parents' explicit or implicit assumptions as they apply to their child's illness. Families who have lost family members to cancer may need very explicit explanations that a parent's or grandparent's experience with prostate or lung cancer may have little in common with a child's diagnosis of cancer.

In the context of a new diagnosis, most parents will experience many intense emotional reactions and may even report psychiatric symptoms of acute stress.[5,89] They are typically frightened and anxious about their child's prognosis and distraught at the thought of their child's physical suffering. If many days or weeks elapse between the child's initial symptoms and the diagnosis, parents may feel angry at medical providers, whom they believe "missed the diagnosis" or did not listen to them or to their child. Parents' belief that there was a delay in diagnosis may also contribute to feeling angry at themselves. Parents are ordinarily active agents in shaping every aspect of their child's care and well-being and may feel quite dismayed at how helpless they feel to protect their ill child. This sense of responsibility may lead many parents to feel responsible for their child's situation, perhaps blaming themselves for not bringing the child to medical attention earlier or for not understanding the significance of a child's initial symptoms.[2,7,8,90,91] In some cases this sense of responsibility and the need to understand the cause of the child's illness may make parents (or other family members) wonder if they themselves are responsible for the cancer. Examples of these thoughts, many of which are not entirely rational, might be wondering if allowing their child to use certain electrical devices, or bringing some kind of contamination into the home from a work site, may have contributed to the cancer.[2,7,8,91] For families coping with neurofibromatosis, Li-Fraumeni syndrome, or other genetic predispositions, a child's diagnosis of cancer may weigh more heavily on parents and leave them more vulnerable to psychosocial distress. The psychosocial care provider can play a crucial role in helping families reframe these difficulties, which will allow them to cope more effectively. In addition encouraging families to pursue a consultation with a genetics counselor can be an important intervention in helping families gain increased knowledge about the genetic predisposition to cancer and develop strategies to decrease stigma and fear and increase appropriate management of risk. Listening to the family in crisis and providing reassurance can be the most useful responses for all members of the care team. Normalizing parents' reactions by letting them know that parents almost universally feel overwhelmed and that intense emotional reactions are normal responses to their child's illness can help reassure them that they are not "going crazy" and they won't be judged for their reactions by the care team.[2,3,7,44,92,93] One reason parents feel overwhelmed is their awareness that they are facing a more complicated, frightening, and demanding challenge than they may have ever faced before. Although it is helpful to acknowledge the feeling of facing this seemingly overwhelming challenge, it is also useful to let parents know that families do cope well, and with some assistance and support, there is every reason to believe their family will cope successfully, even though that may be difficult to imagine at the beginning of treatment.[52,94-97]

During the crisis of diagnosis, many families will benefit from concrete structuring from the care team. Parents often need to be encouraged to focus on their own self-care and may need encouragement to mobilize their social supports to meet their acute needs, such as arranging extended time off from work or asking friends and extended family to help with other tasks. Many parents can benefit from some active problem solving,[52,92,98-100] with staff helping them to identify needs, generate possible solutions, and then select and implement a potential solution. Social workers and resource specialists on the care team may be helpful in identifying sources of practical support (e.g., transportation, meals, and lodging), sorting through insurance issues, and helping solve problems with regard to meeting the needs of the patient and family.

Occasionally some parents experience such a strong need to act in the face of their child's illness that they make decisions that can be premature or even impulsive. For example some parents have quit their jobs, mortgaged their homes, or moved their residence even before knowing the details of their child's treatment and taking time to consider these major life decisions. Although parents need to decide for themselves how their family will adjust and cope with the demands of the child's illness and treatment, it is appropriate for members of the care team to caution against making impulsive decisions and support them in making short-term plans for managing the health crisis that can be revised as circumstances change or new information becomes available.

During the crisis period parents can experience a wide range of intense emotional reactions. In most cases parents' reactions can be managed with education and support from the care team. Specialized services from a psychosocial care provider, usually a psychologist or social worker, can be particularly useful in helping parents identify and begin to cope with their emotional reactions.[92,101-103] Many of these reactions will be of short duration because parents often report feeling less overwhelmed after they have heard a definitive diagnosis and can focus on the demands of a treatment plan. Research has demonstrated that the initial psychological distress experienced by mothers at the time of diagnosis tends to steadily improve as long as 6 months after the diagnosis.[104] In rare cases parents may have emotional reactions that are more enduring or problematic,[2,12,105,106] which may require more targeted intervention during the crisis period. Situations involving confusion about the child's diagnosis or requiring a prolonged diagnostic evaluation

TABLE 73-1 Factors Associated with Increased Psychosocial Distress

Family Factors	Disease Factors	Environment/ Resource Factors
Single-parent families	Unclear diagnosis(es)	Financial problems (e.g., job loss or debts)
Preexisting chronic or mental health	Poor prognosis	Isolation (e.g., lack of family and/or problems with peer support)
Concurrent illness or injury in family (e.g., parent or sibling illness)	Prolonged or intense treatment(s) (e.g., bone marrow transplant)	Language differences (e.g., foreign national or immigrant)
Marital problems (e.g., separation and/or divorce)	Disfiguring disease or treatment(s) (e.g., amputation)	Transportation (e.g., no car to get to the hospital)
Family problems (e.g., emotional or learning difficulties)	Disease status (e.g., relapse or recurrence)	Minimal or no health insurance
Recent stressful life events (e.g., job and/or school problems, a move, or relocation)		

Modified from Hersh SP, Wiener LS: Psychosocial support for the family of the child with cancer. In Pizzo PA, Poplack DG, editors: Principles and practice of pediatric oncology. *Philadelphia, 1989, J.B. Lippincott Company, p. 897–891; Kazak AE, Cant MC, Jensen MM, et al: Identifying psychosocial risk indicative of subsequent resource use in families of newly diagnosed pediatric oncology patients.* J Clin Oncol *21:3220–3225, 2003; and Lansky SB, List MA, Ritter-Sterr C: Psychiatric and psychological support of the child and adolescent with cancer. period are more stressful for parents and may be more likely to cause significant distress. Similarly parents who are managing other significant stressors such as having a parent or other family member with medical needs and parents with preexisting psychological problems will be more likely to have symptoms that interfere with their ability to function (Table 73-1).[2,12] Examples of these problematic reactions might include manifesting signs of clinical depression or anxiety, not being able to care for themselves adequately (i.e., not sleeping or eating), or being so frustrated and angry that they cannot consistently collaborate with medical providers. In these situations in which parents' reactions will have a negative impact on the child and have the potential to interfere with the treatment process, it is important to address the situation directly with the parents and make appropriate referrals for intervention.

Interventions for parents experiencing these problematic reactions may require more intensive services from some members of the care team, as well as consultation with and referral to other individuals. The underlying problems may predate the child's cancer, but the focus of intervention during the crisis of diagnosis may appropriately be alleviation of symptoms. Parents showing signs of severe distress should be evaluated by an appropriate psychosocial team member or be referred to a mental health provider who can assess their psychological status and refer them for any urgent intervention they may need. In addition to supportive therapy and the problem-solving approaches previously described, psychopharmacologic intervention may be particularly helpful for parents who have severe anxiety or depressive reactions, severe sleep disturbance,[107,108] or a preexisting psychopathologic diagnosis. Pastoral counseling may be useful for parents whose faith is an important source of support and for those experiencing a "crisis of faith" as they struggle to make meaning of their child's illness.[109-111]

Children's Reactions to Diagnosis

Children will react to their diagnosis and initial treatment on the basis of their developmental level, their own individual temperament and past experiences, and to a large degree on how their parents cope with the new diagnosis and treatment.[112,113] Typically the infant, toddler, and especially the preschooler will be more concerned about changes in routine and the normal home environment, separation from family, especially the primary caregiver, and bodily intrusion through physical examinations and medical procedures for diagnostic or treatment purposes. Strange environments will disrupt normal awake/sleep patterns, and sleep deprivation can reduce the child's normal self-regulation effectiveness. For example infants who had been able to sleep through the night at home might have constant awakenings. Separation from the primary caregiver(s) then becomes an even larger issue if the parent is not present during the night or during bodily intrusion episodes to help comfort the child. Clearly this need for the parents suggests that, when possible, it is better for parents to create "shifts" to be with the child as much as possible, day and night. Such parental support also means that the issue of support for parents, both emotionally and in practical ways, needs to be addressed.[114] Stressed parents who cope poorly will not be able to help their child self-soothe well.[15,115]

One issue that the medical team can address is the manner in which examinations and procedures are carried out. For example Chen and colleagues[116,117] found that children had memories of stressful and painful procedures that affected their experience and behaviors during subsequent procedures. Asking the parent to leave the room while a team of doctors and nurses in white coats enter the child's room to carry out examinations is more likely to help create an uncooperative child who will become conditioned to be anxious around anyone with a white coat. Having one member of the team develop a relationship with the child, from toddlerhood through adolescence, will be helpful in establishing the child's trust of the nonfamily "team." Establishing a system for families in the hospital that sets clear guidelines for providers as they enter a child's room can prevent significant distress. For example psychosocial providers or child life specialists can create a sign for the door that reminds providers to introduce themselves when they enter the room, let the child know up front what is going to be required of them, and hold medical discussion outside the room when appropriate. Respecting such requests fosters rapport, reiterates the message that the child and family are part of the team, and promotes the sense of being "heard" by the medical team.

For the very young child, procedures that can be performed competently and quickly while distracters are present (e.g., iPad apps, bubbles, party blowers, cartoons, and stories) can reduce fear of future procedures and help the child develop a sense of control and cooperation. The use of positive reinforcement is helpful in an effort to pair "scary" novel and intrusive experiences with positive, pleasurable experiences. The use of behavioral strategies (e.g., breathing, relaxation, imagery, and behavioral charts) can provide parents with ways to support their child in these novel and intrusive situations and help the child develop a sense of security and mastery, and they give parents the opportunity to feel successful in the context of challenging medical demands. Additionally it may be useful to encourage the family to bring in a "transitional object" for their child (e.g., a favorite blanket or stuffed animal) to bring the familiarity of "home" into the hospital.

School-aged children will be interested in concrete answers to their questions about hospitalization, expectations with regard to medical examinations, and specifics about what to expect in unfamiliar situations. Encouraging parents to answer questions directly, even when the topics may be uncomfortable, will foster open communication and minimize the chance that the child will create "answers" based on faulty assumptions that can be anxiety provoking.[118-120] Parents should be reminded that this is not a one-time discussion and that providing their child with information, even upsetting information, can decrease uncertainty about the illness and potentially improve psychological functioning.[121]

While children develop an increased understanding of their illness, they may ask, "Am I going to die?" Psychosocial providers can help guide parents in providing answers to this question based on a child's age and diagnosis. It is important for parents to acknowledge the severity of the disease while highlighting the fact that the medical team has a treatment for the illness. Answers to this question will vary based on a child's medical condition, particularly in the case of relapse. Exploring a child's thoughts and fears around illness and death can be helpful; however, providing reassurance that he or she will be well taken care of and not left alone and that his or her symptoms will be treated is critical.[119]

Adolescents are likely to want to know more information about their illness and treatment. Simple responses to questions often will not satisfy them, and parents will need to understand that adolescents may potentially turn to alternative sources beyond their parents for important information. A child or adolescent who has formed a relationship with a member of the treating team can ask questions of that team member that might seem difficult to ask parents.[122,123] Some adolescents feel a need to "protect" their parents from more stress by not acknowledging to their parents their own fears, anger, and worries. Encouraging adolescents to talk about what they have learned from their medical providers, the Internet, and their peers will help eliminate misinformation and confusion while empowering adolescents to seek information in their own way. Developing a sense of mastery over the medical information can lead to a feeling of control and confidence that can be helpful for teenagers.

Finally, children of all ages often regress when they are scared, and parents need to know that changes in the child's behavior are not unusual.[124] Psychosocial providers can normalize behavioral reactions for parents and subsequently minimize the distress associated with particular behaviors. For instance a preschooler who has just been toilet trained may begin having accidents, and it is imperative that parents recognize that this behavior is a normal response to a stressor and that they should not focus too heavily on that behavior during a time of crisis. The following guidelines are related to children's reactions to diagnosis and treatment:[125]

- Many parents need help talking with their child, who is often scared and needs some explanation and education along with his or her parents.
- A variety of disciplines, such as child life, nursing, social work, and psychology, can all be helpful to parents, siblings, and pediatric patients. Interventions relating to preparation for medical procedures, supportive work with parents and other family members, and psychoeducation are important. Connections with other children and families who are having similar experiences can be helpful.
- Keys to getting through diagnostic procedures are good preparation and good pharmacologic and psychological pain and anxiety management.

Education and Information about Treatment

Most treatment regimens put an enormous information burden on the family. Children are often treated with several modalities (such as surgery, radiation, and/or chemotherapy) and may receive a large number of medications, as well as a variety of blood tests and other diagnostic procedures. Although adolescents may be active in their own care to some extent, parents are responsible for understanding and managing their child's treatment, especially during outpatient phases of treatment when parents will need to work with home care agencies, administer treatments themselves, and monitor their child's health. To meet these demands, parents require detailed information about their child's treatment regimen and reactions that can be expected.[101,102,126,127] Most of this detailed information will be provided by nursing and medical care providers. Patients and families are generally quite resilient and successfully accommodate even the most demanding treatment regimens, but initial apprehension about being able to understand and implement these regimens is common. Staff may need to present information several times and reinforce verbal exchanges with written materials. While remaining optimistic and encouraging families to develop competence, it is also important for providers to recognize the complexity of what they are asking of families and the burden it imposes. Normalizing the common feelings of anxiety and "information overload" while focusing on problem solving in the face of new demands is an important role for the psychosocial clinician. Talking with other families who are undergoing similar treatment can be particularly helpful,[102,103,126,128,129] and many centers offer education and support groups for new patients and families. In addition a wide variety of books useful to parents[130-135] and helpful for patients and siblings[136-146] may be available from hospitals, libraries, and booksellers.

Among older children and adolescents, interest in or openness to learning more about their illness and treatment can be highly variable. Because they have more developed cognitive and language abilities than younger children, older children can ask more questions and understand more about their treatment, and like parents, they may receive educational information from nursing staff as previously described. To the extent of their capabilities, adolescents should be encouraged to participate in their own treatment by learning about their medications and schedule, helping with simple self-care activities such as routine care for a central venous line (CVL), and learning the best ways for them to cope with adverse effects or medical procedures. In some cases adolescents may not be interested in some of this information or may feel disinclined to assume even basic self-care responsibilities. It is not uncommon for adolescents to feel overwhelmed by information about their disease, particularly given the typical developmental milestones they are attempting to navigate.[147] Feelings of distress associated with a loss of autonomy may lead adolescent patients to become more withdrawn. It can be helpful to empathize with adolescents' plight of feeling "pushed around" while actively working with them to develop adaptive coping strategies that may lessen their feelings of helplessness. It is often important to point out that although many aspects of the situation cannot be changed (i.e., you have cancer, you need treatment, and the treatment will cause you to miss school), some aspects can be changed (e.g., you can maintain ties with friends through texting, social media, or visits, you can keep up with school work, and you can plan a party or an outing to celebrate an upcoming treatment milestone). It can be overwhelming for parents to include adolescents in difficult conversations about their illness and treatment, but adopting a model of shared decision making with adolescent patients in the early stages of treatment can empower patients, improve comprehension and understanding of the treatment plan and toxicities, and enhance communication among parents, patients, and providers.[148,149]

The Internet

In addition to obtaining medical information from medical teams, outside consultations, and family and friends, parents also gather information from the Internet. The ability to access information quickly and conveniently is appealing to parents who can feel overwhelmed during medical discussions. Given that it is common for patients and parents to use the Internet to gain knowledge about their disease and treatment, it is crucial that medical providers help families identify appropriate websites where they can access accurate information. In particular providers should consider providing parents with a list of recommended websites. These websites may include local resources affiliated with the treating institution, disease-specific resources, and general pediatric cancer sites facilitated by reputable organizations such as the Children's Oncology Group, Pediatric Cancer Research Foundation, National Cancer Institute, and the American Childhood Cancer Organization (e.g., www.curesearch.org, www.pcrf-kids.org, www.cancer.gov, and www.acco.org). The National Cancer Institute website offers educational materials in both English and Spanish. Ensuring accuracy of information is important not only for the parents' understanding but also for that of adolescent patients who frequently access the Internet.[150,151] Using a search engine to research a cancer diagnosis and treatment does not always lead to relevant content.[152] In addition the readability of websites is highly variable,[152] and the information provided on some websites may be difficult for some parents and patients to understand, potentially leading to additional confusion at an already challenging time. Potential exposure to difficult material (e.g., prognosis, individual narratives, and grief) without the immediate support of the medical team can be a particular concern. Having a discussion with families about the dangers of exploring too broadly on the Internet early in the diagnosis and treatment period is important so they can avoid exposure to potentially upsetting information.

Despite the potential challenges associated with gathering information via the Internet, this avenue provides some clear advantages for parents and patients, and research is burgeoning in this area to best meet the needs of the families.[153] Open patient-physician communication with regard to gathering information, asking questions, and researching treatment options and plans can help minimize confusion or distress based on misinformation obtained via the Internet. This approach represents a movement away from the more paternalistic approach, and medical providers can encourage families to conduct their own research and come back with questions or concerns.

ADJUSTING TO TREATMENT

While the child and family come to understand the diagnosis and treatment plan, their focus begins to shift from managing uncertainty to coping with the demands of treatment. Although parents in particular will continue to worry about their child's prognosis for years to come, the day-to-day demands of treatment along with the other demands of work and family life become increasingly salient. Families often experience a subjective sense of relief associated with a reduction in uncertainty, but they may also have an increased sense of burden. During the crisis of a new diagnosis, parents usually take time off from work and temporarily set aside many practical concerns. With the initiation of treatment, parents and children typically need to return to their regular roles and responsibilities while also taking on the new responsibilities associated with treatment. During this period of adjusting to treatment, families often benefit from continued psychosocial assessment, education, and support. In actual practice, encounters with the patient and family will blend these three objectives, especially at the initiation of treatment, but they are presented separately here for clarity of presentation.

Psychosocial Assessment of the Patient and Family

Experienced psychosocial care providers generally have a way of conducting an assessment that is comfortable for them and generates the relevant information. For illustrative purposes, a general approach to the assessment interview will be outlined here and in Box 73-2. The process of the interview should include time for the family members to speak about their concerns, but the provider will need to actively direct the conversation to ensure that the necessary topics are covered. In an interview with both parents if possible, the provider may begin by asking about the general family history and then focus on the patient's premorbid functioning, a developmental history, and the relevant history of any other children. Details of the patient's functioning at school and relationships with peers and siblings should be solicited, as well as prior experience with stressful situations and any behavioral, developmental, or emotional concerns prior to the cancer diagnosis. In learning more about the parents, it is useful to know the basic outline of their families of origin, their current work or family roles, and any religious and cultural traditions that may affect their ability to cope with the illness. It is important to know if the family has had to cope with significant stressors in the past and if any other significant problems exist in the family at present. If the parents are divorced or not married, understanding this history, as well as the practical and legal aspects of any custody arrangements, is critical. Understanding the family's practical and social resources is also an important component of the assessment.

The assessment of the pediatric patient will vary significantly depending on the child's age and medical status. With an infant or toddler, the child will be seen along with the parent, and the goals may be to observe the parent-child interaction, appreciate the child's temperament and reaction to the medical setting, and establish the psychosocial provider as a friendly and nonthreatening presence. With older children the goals will also include directly assessing their reaction to their illness as they are able to express it verbally or in play. Because children typically have met many health care providers in the hospital or clinic, it is important for the provider to begin by introducing himself or herself, describing the purpose of the meeting, and reassuring the child that there will be no medical examination or use of needles during the meeting. With most children, even into adolescence, the assessment can be greatly facilitated by including action, such as unstructured play, a walk in the hospital, a craft, or a game.

With preschool and school-aged children, familiar activities such as drawing or symbolic play with dolls or puppets can serve the dual purpose of engaging them and providing an expressive medium through which they can relate their concerns. When children are engaged in this type of play, the provider can assess them by observing or participating in the play, as well as by asking them questions about their illness, their medical care, and how they are coping (e.g., "What has been the hardest part about being a patient?"). For older children, questions

Box 73-2 **Psychosocial Assessment Interview of the Patient and Family**

STRUCTURE OF INTERVIEW

- One to three intake meetings with patients and parents, conducted by a mental health professional.
- Meetings held in a relaxed, nonthreatening setting.
- Written summary of assessment to be shared with the treatment team.

ASSESSMENT CONTENT

ILLNESS CONTEXT

- Initial presentation of the illness.
- Diagnosis, prognosis, and anticipated treatment.
- Previous child and family experiences with physical health problems and behavioral problems.
- Family's coping, especially cohesiveness, communication style, and ways of resolving conflicts.

CHILD PATIENT

- History
  - Developmental—milestones, temperament, delays.
  - Medical—previous diagnoses and responses to medical care.
  - Behavioral—energy level, moods, and sleeping/eating habits before and after the illness.
  - School and Social—relationships with parents, siblings, and peers, educational history, and functioning in school.
- Response to diagnosis and coping style.

PARENT AND FAMILY

- Background and History.
  - Basic structure and involvement of extended family.
  - Sources of social support.
  - Relationships, sources of conflicts, and cohesion.
  - Physical and mental health.
  - Sibling relationships.
  - Parent education and employment.
  - Religious beliefs and cultural traditions.
  - Parenting styles.
- Initial Response to the Diagnosis
  - Knowledge and understanding of diagnosis.
  - Level of distress—emotional and physical symptoms.
  - Strength and vulnerabilities during the crisis.
  - Coping styles and experienced need for support.
  - Expectations and sources of stress and anxiety.

RESOURCES

- Housing.
- Names and ages of family members living at home (e.g., siblings and grandparents).
- Available support for work, neighborhood, and school.
- Financial status.
- Health insurance.
- Involvement within the community and social supports.
- Travel time and transportation to treatment center.
- Resources available during the child's ongoing medical treatment.

Modified from Hersh SP, Weiner LS, Figueroa V, et al: Psychiatric and psychosocial support for the child and family. In Pizzo PA, Poplack DG, editors: Principles and practice of pediatric oncology*, ed 3, Philadelphia, 1997, Lippincott-Raven, p. 1241–1266.*

about life before cancer including friends, hobbies, and school activities can be a good starting place before asking about their illness and how they are coping with their medical care. It is important to ask older children directly about any worries, anxiety, and symptoms of depression or hopelessness, as well as how the adults involved in their care can best help and support them.

Adolescents may have very personal concerns about how their illness will affect them, such as by causing them to miss an upcoming social event or interfering with a particular friendship or a dating or romantic interest; such concerns may not be immediately apparent to the parents or the medical team. Asking explicitly about what they anticipate will be difficult about their treatment plan is an important part of the assessment, as is inquiring about ways they believe they will deal with the challenges of treatment. Family systems often shift in response to a child's illness, and it can be important to understand the changes adolescents may have experienced and how those changes may be affecting them, especially because adolescents in treatment may become more dependent on their parents and spend more time with them than they normally would. Because adolescents often believe that the patient role limits their privacy, agreeing ahead of time with parents and adolescents about what information from the adolescent interview will need to be discussed with parents and what information everyone agrees can be kept confidential will be important.

After concluding the interview with the patient, it is important to give feedback to the parents about what was discussed, the child's main concerns, and generally how the patient is coping with the illness and the demands of treatment. If the psychosocial care provider has specific recommendations for further assessment or intervention, they should be explained to the parent and patient. For illustrative purposes this description has emphasized the information that should be gathered in the assessment, but the process of the interview should accommodate both the goal of assessment and the goals of education and support.

Support for Parents and Families during Treatment

Families may require very different levels of psychosocial support during treatment, and even within a single family, needs will vary over time. Ideally psychosocial support can be offered to patients and families in a flexible way that can be tailored to their individual needs. This flexible approach requires some ongoing assessment and communication with families about their coping and adjustment, as well as the ability to quickly adjust the level of services offered to each family. Families typically require more intensive involvement from the psychosocial care provider during the diagnostic period and the beginning of treatment,[104,154] as previously described. Some families may continue to have high levels of emotional distress or ongoing problems adjusting to treatment (Table 73-1) and will require continued regular meetings with a psychosocial provider, but many families will not have this need. For families who are adjusting adequately to the routine of treatment, their need for psychosocial care often decreases. For these families the psychosocial care provider may briefly check in with patients and parents in the context of their regular medical care. These brief visits may be useful for assessing their adjustment and reinforcing previously offered suggestions and interventions. The psychosocial team may also offer information about educational and support groups, which can be particularly helpful for parents adjusting to treatment.

With any decrease in intensity of direct psychosocial involvement, care should be taken to ensure that patients and families do not feel abandoned by the psychosocial care provider. In most clinical settings a team model is used in which medical providers and psychosocial clinicians are in frequent communication so parents can be assured that when important medical changes occur that have potential psychological implications, psychosocial care providers will be informed and will intervene as appropriate. It is important to review with parents the expected challenges that may arise during the course of treatment (described in the next section) and encourage them to contact the psychosocial care provider if they need assistance with these or other issues that arise.

If some adjustment problems arise during the course of treatment, such as problems at school or difficulties with discipline, the psychosocial care provider should offer symptom-focused interventions such as educational support, behavioral intervention, or other counseling. Typically this intervention may involve a small number of sessions delivered as part of the patient's regular medical visits or a referral for short-term therapy within the treating institution or in the community. While the presenting issue is resolved, children and families will typically return to their previous level of adjustment, and the intervention can be tapered off and discontinued.

Some families will experience brief periods of intense emotional distress related to the stress of cancer treatment. These episodes may occur when they are facing painful or unpleasant therapies or when treatment complications arise. Intervention for moderate to severe distress could include an increase in the intensity of routine psychosocial support services, consultation with additional mental health providers to provide crisis intervention, psychiatric assessment, and use of psychopharmacology for patients or other family members. In the outpatient setting, referral to outpatient providers in the community will also be important.

Some children and families will require a more intensive level of psychosocial care consistently throughout treatment. In most cases these families have high emotional distress, multiple stressors, or limited resources, which can often be recognized during the psychosocial assessment (see the previous section). For most of these children and families, regular ongoing psychosocial services will need to be provided for much or all of the treatment period. In these cases the psychosocial care provider should consider several types of intervention, such as play therapy, cognitive-behavioral treatment, and parent guidance. Referral to other specialists, either within the treating medical center or in the community, is useful when specialized services are needed (e.g., psychopharmacology) or the child or family needs more intensive treatment than can be accommodated within the oncology clinic. Referral for outside services such as psychopharmacology or individual or family therapy is particularly useful in cases of some preexisting mental illness, family conflicts, or multiple major stressors.

Few families will present with psychological distress or behavioral problems that cannot be successfully managed with routine psychosocial care along with some provision for brief intensive interventions.[14] Usually families that cannot be managed in this way are those with many other stressors occurring at the same time or families that include an individual with a preexisting psychiatric disorder, such as major mental illness, substance abuse, or severe personality disorder. When families have multiple stressful events occurring simultaneously, such as a second illness in the family, a major loss, or economic instability, they may require more psychosocial support at the cancer center, as well as referral to additional outside agencies. Preexisting psychiatric disorders should be evaluated as part of the psychosocial assessment. Vulnerable persons at high risk for worsening of symptoms or relapse should be referred for mental health treatment or counseled about the need to access treatment quickly if symptoms recur. Communication between the psychosocial providers on the oncology team and outside mental health providers can be helpful to share a common understanding of the child's cancer treatment status and updates about the mental health status of the family member in treatment, but this communication needs to be undertaken in a limited manner that preserves privacy.

Families with consistently active psychosocial needs can present a challenge to the care team because of their emotional distress and the demands they may make on staff time. By providing consultation to the nursing and oncology staff, the psychosocial care provider can help the treatment team formulate an understanding of the family's needs and coordinate an appropriate and consistent response.

School

Shortly after diagnosis, questions often arise regarding the child's academic needs and how these needs will be met. Will the child be able to attend school, or will a tutor be provided until the child is able to return to the classroom? How is the treatment course likely to interfere with the child's ability to succeed academically? Will the child meet the academic requirements to be promoted to the next grade, or is it likely that the child will need to repeat a grade? These types of questions will need to be addressed by the family, school, and medical team.

School represents an important locus for the child's cognitive, social, and emotional development, and maintaining participation in or reconnecting with school should be a priority when planning the child's treatment and care.[155,156] For the child resuming school responsibilities can feel overwhelming given the demands of treatment. Adverse effects of treatment can have a negative impact on motivation, concentration, and processing speed, making the transition back to school challenging. Despite the issues resuming academic work promptly will minimize the disruption to academic progress and maximize the child's ability to reengage in school-related tasks. Because many children will be unable to attend school during at least part of their treatment, home- or hospital-based tutoring along with a structured schedule that provides the child with the exact time and duration of school-related work often promotes compliance.

Parents and caregivers must commit themselves to providing the necessary structure and support to promote the child's academic progress, even when juggling numerous other responsibilities. Parents should be encouraged to let the tutors be responsible for assisting children with their academic work and avoid the urge to "help" children with their homework. Extended absences from school can lead to increased anxiety at the time of reentry and potential avoidance behavior. Psychosocial providers can work closely with patients, parents, and school personnel to help ease a child back into school while addressing anxiety issues.

The medical team is often called upon to provide the school with relevant information about the child's ability to attend to academic responsibilities or any vulnerability the child may have as a result of treatment (e.g., risk of infection, susceptibility to illness, and potential cognitive and/or physical deficits). School personnel may be especially anxious when the child initially returns to school, resulting in multiple calls to the treating physician. Parents will play a critical role in educating the school about their child's situation and advocating for the child's needs. Many parents benefit from consultation with psychosocial providers about how best to negotiate the return to school and often find written guides for parents[131,135] to be helpful. Some clinics have established "school reentry" programs in which staff members (e.g., child life, nursing, and mental health professionals) visit schools to present information to teachers and classmates about the child's diagnosis and treatment.[157-159] This proactive approach can be effective in providing medical information to the school nurse and other staff, as well as helping to answer questions that teachers and classmates may have about the returning child's condition and needs. In most cases, these efforts will result in a plan for school reentry that is appropriate and comfortable for the child and parents.

If a child will need specialized instruction because of his or her illness or consequences of treatment, an individualized education plan (IEP) will be required. Federal laws, as well as the laws in several states, require that children with disabilities be accommodated in their schools,[160-162] and parents who suspect their child will need some accommodation should speak with the school's special education director and refer to their state's Department of Education website for information about the special education procedures in their location. In most cases, parents will need to begin the process by making a written request for an evaluation. This evaluation is conducted by the school, often with significant input from medical and psychosocial providers involved in the child's cancer treatment. If as a result of the evaluation the child is found to be eligible for special education services, an IEP will be developed and implemented by the school. If the child does not qualify for specialized education services, he or she may still qualify for accommodations under the Federal Rehabilitation Act, often referred to as a "504 plan."[163] A 504 plan may ensure appropriate accommodation for problems in physical mobility, fatigue, attendance, or other needs of the child that affect school performance but do not require specialized instruction. The IEP determination process can be time consuming and frustrating for parents who have already had to negotiate complex health and insurance systems for their child. Parents should educate themselves about their state's education laws and the federal laws that govern accommodation of children with medical conditions and disabilities[161,162,164] and consult with psychosocial providers who understand the system and academic needs. If significant issues are encountered in securing appropriate accommodations, parents may want to consider enlisting the services of educational advocates[165] to assist them in negotiating with their school.

Peer Relationships

Relationships with peers at any developmental level provide a child or adolescent with crucial components for successful adaptation, including a sense of connection, friendship, and support. This role of peer relationships is as true for children diagnosed with cancer as it is for their healthy peers. Several research studies have focused on the role of peer relationships in the coping and adjustment of children and adolescents with cancer.[166-170] Although parents have been identified as a primary source of nurturance, support, and information for children with cancer,[168] research findings suggest that relationships either with healthy peers or with peers diagnosed with cancer are also extremely important. For example adolescents diagnosed with cancer who report close friendships have been noted to experience increased social support,[148,167] increased feelings of hope,[171] and an ease in communicating about their cancer experience.[168] Additional research suggests that adolescents with cancer view peer relationships as vital to the continued development of their independence and identity, which are areas that can easily be derailed by illness.[169,172]

Studies examining other aspects of peer interactions reveal somewhat mixed results. Some findings have suggested that both children and adolescents who are diagnosed with cancer have fewer friends than their same-aged peers[168,173] and that this trend may continue after treatment has been completed.[174,175] Other findings have indicated that children diagnosed with cancer may be socially isolated and withdrawn,[176] despite the fact that their popularity and number of friendships are comparable with those of their peers.[177] Whether these results reflect a change in the nature or quality of peer interactions because of illness-related factors (e.g., prolonged hospitalizations, significant school absences, or the inability to engage in recreational activities) is difficult to determine.

Given the importance of peer relationships in the course of normal development and the potential for disruption to these relationships during diagnosis and treatment, members of the medical team must support connections with peers whenever possible.[178] This support may include encouraging parents to facilitate peer interactions at home and at the hospital and to work with educators to establish opportunities for the child to visit school for lunch or a single class so that peer connections can continue when the child is not well enough to attend school regularly. When appropriate, medical staff can also support an adolescent patient who wishes to share the clinic experience with a friend and invite the friend to attend an outpatient appointment. These opportunities, although often limited by the impact of treatment, help children with cancer and their peers maintain crucial relationships that will improve posttreatment adjustment. Encouraging parents to allow children and adolescents to have contact with peers who are also diagnosed with cancer can be extremely important. The Internet and social media sites can be very helpful when treatment prevents school attendance. Although parents will want to ensure that the sites that children are using are appropriate, technology that provides ways for children to share pictures, play video games with friends online, video chat, or text can be important ways for them to maintain contact with peers. Participation in summer camps or activities offered through the clinic or hospital provide opportunities for children and adolescents to enjoy activities with peers who have a shared medical experience and can improve self-concept.[179]

EXPECTABLE CHALLENGES DURING TREATMENT

Although psychosocial needs vary considerably between families, certain challenges commonly arise while children progress through their cancer treatment. Some of these challenges are directly related to coping with the demands of treatment, and others have to do with managing the ongoing demands of work, school, and family life while also managing the added stressors of cancer and its treatment. Understanding these challenges can help families anticipate when and how they may need to mobilize their resources. Psychosocial care providers can provide anticipatory guidance with regard to these concerns and facilitate access to appropriate intervention as needed.

Coping with Treatment and Adverse Effects

About 25 years ago, adolescents with cancer reported that their treatment and its adverse effects were the worst things about having cancer.[180] The nausea and vomiting accompanying chemotherapy and the pain associated with procedures such as lumbar punctures and bone marrow aspirations were particularly distressing.[181-184] Treatment of these adverse effects has significantly improved since then. Fairly effective antiemetic drugs are available, and for most patients, procedures are carried out after induction of light or deep sedation or general anesthesia. Despite these advances, children still find chemotherapy, radiation therapy, and various procedures to be very unpleasant and a source of significant apprehension and distress.[185-190] A variety of studies have documented the effects of hypnotherapy, memory evaluation, and other behavioral therapies in reducing adverse effects in this population.[116,191-198] Reducing procedure-related pain, anxiety, and nausea and vomiting associated with chemotherapy and radiation therapy is critically important for reduction of risk factors for posttraumatic stress disorder, long-term pain, and psychological distress in survivors.[1,105,199-210] The topics of pain and symptom management are treated more extensively in Chapter 71.

Maintaining Child and Family Routines

Basic Needs

In the aftermath of a pediatric cancer diagnosis, family members must find ways to attend to basic needs and responsibilities. Although this process can be difficult, family members must eventually shift their focus from the diagnosed child and the isolation of the hospital room to life outside of the hospital. For many families, this process may include working to understand their insurance coverage and medical costs or negotiating with employers regarding the use of vacation or sick leave to care for their child. Grocery shopping, cleaning the house, paying bills, and keeping up with the laundry are additional activities that constitute a typical week for the average family—activities that were likely ignored or attended to by others during the early stages of diagnosis and treatment.

Transitioning from managing a medical crisis to managing the more mundane tasks of everyday life can be challenging but can also reintroduce a sense of normalcy. The reality of financial pressures can necessitate the transition back to work and create additional stress on the family system. Even with excellent insurance coverage, the costs associated with treatment can be significant, particularly for parents or caregivers who have been away from work since the child's diagnosis.

After the initial phase of treatment, parents and caregivers typically attempt to piece together a plan that will allow the family to function effectively and attend to basic needs. This plan will likely take into account the child's medical appointments (both scheduled and unscheduled), the child's school reentry and ongoing attendance, parent or caregiver work responsibilities, attention to the academic and social needs of the child and the child's siblings, and other family commitments and responsibilities. The ability of the family to successfully develop and implement this plan is dependent upon a number of factors, including characteristics of individual family members (e.g., coping style, organizational skills, and cognitive abilities), the functioning of the family as a whole (e.g., cohesion, adaptability, and flexibility), and the response of community members (e.g., a supportive network of friends, the flexibility of employers, and the commitment of school personal).

Understandably attending to basic needs and securing resources is crucial to the successful treatment of the child and the overall functioning of the family, and thus it is essential that members of the medical team support the family in their efforts to meet basic needs whenever possible. This support might include the timely completion of medical forms that will facilitate the implementation of educational services, helping eligible families secure appropriate financial resources, helping families access specialized nursing services in the home, allowing for flexibility in the scheduling of appointments to accommodate a long commute to the clinic, or simply being willing to listen empathically when parents discuss the challenges they face.

Discipline

The diagnosis and treatment of cancer in a child can disrupt every facet of family functioning, including expectations that parents have about their child's behavior and their ability to effectively set limits and exercise appropriate discipline. Understandably many parents and caregivers are unable or unwilling to discipline their children given the difficult medical circumstances in which the family finds itself. A child's behavioral outbursts that may include hitting, kicking, and screaming are seen as a natural consequence of a very difficult and unnatural situation. Disruptions to daily routines, invasive medical procedures, medication adverse effects, and the child's "just feeling lousy" can provide more than sufficient rationale to let the child's behavior remain unchecked. In addition parents and caregivers may be wrestling with their own feelings of guilt, sadness, anxiety, or exhaustion that can make it increasingly difficult to impose behavioral expectations, even for parents who previously demonstrated consistent and appropriate behavior management techniques with their children.

For children whose parents or caretakers are unable to provide effective discipline during treatment, the short- and long-term consequences can be disastrous. For example a child who does not experience appropriate limit setting may feel out of control and unsafe, leading to further behavioral disruption. Behavioral outbursts and noncompliance can interfere with medical care and have an impact on effective working relationships with staff. Inappropriate behavior can spread quickly to siblings who learn through observation that parental authority has been eroded, increasing the overall chaos within the family system. By the time the child's treatment ends months or years later, it can be extremely difficult, if not impossible, to reestablish expectations for appropriate behavior.

To avoid these short- and long-term consequences, parents and caregivers need to provide clear and consistent expectations for their child's behavior as quickly as possible after diagnosis. It is essential to acknowledge to the child that the pain and disruption associated with diagnosis and treatment often causes frustration, sadness, anger and despair and that this is expected. However it is equally essential to convey to the child that expressing emotions through appropriate means is imperative.

Members of the medical team should work with parents to reestablish appropriate discipline practices. During the initial phase of treatment, the team's assessment of the family should include questions about the parents' approach to discipline and strategies that are both effective and ineffective in managing their child's behavior. Understanding parenting styles[211] and the child's prior experiences with discipline can be extremely helpful in predicting possible reactions in both the child and parent. Encouraging parents to utilize an authoritative approach—that is, clear, firm limit setting coupled with appropriate encouragement of independence—will help children be more successful at negotiating the difficulties associated with diagnosis and treatment. A more punitive and authoritarian style will likely increase the anxiety and fear the child is already experiencing, whereas an indulgent or permissive style can foster noncompliance and increased disrespect of others.

A number of behavioral techniques can be used to increase a child's compliance and to minimize disruptive behavior. First, taking the parent aside, acknowledging the challenges of disciplining a sick child, and offering suggestions will be more effective than openly criticizing the parent's poor behavior management in front of the child. When the child's behavior interferes with medical care, staff should encourage and support authoritative parenting. Such encouragement might include staff modeling of behavior management techniques such as giving the child clear instructions ("You need to sit on the table, and you can hold dad's hand"), praise ("I really appreciate how you answered my questions; you've done a great job"), and attention ("Because you were so cooperative and we finished your dressing change so quickly, I have a few minutes to look at your baseball cards, if you'd like to show them to me"). Praise and attention are examples of positive reinforcement, approaches that increase the likelihood that the child will behave the same way in the future.

Behavioral techniques such as "sticker charts" can be implemented with the help of mental health practitioners or child life specialists. Developing a sticker chart includes identifying a behavior the team needs the child to perform (e.g., taking medication), as well as a reward that increases the child's willingness to engage in the behavior. Each time the child behaves appropriately, a sticker is applied to the chart, and after a specified number of stickers have been achieved, a predetermined reward is given. The reward must be given frequently enough that the child experiences the benefits of his or her efforts. When available these techniques should be used in conjunction with psychosocial services from mental health practitioners familiar with the treatment of medically compromised children. Parent education and guidance, as well as counseling or psychotherapy, can be helpful in supporting parents and caregivers in maintaining discipline while providing children with appropriate outlets for their feelings. Many parents will benefit from referral to parenting support groups and books about effective discipline.[212,213]

Siblings

The siblings of children diagnosed with cancer have a unique and often difficult road from the moment a brother or sister is diagnosed with cancer. The uncertainty experienced in the context of a cancer diagnosis and the impact it has on a family system has significant implications for siblings. Siblings spend a significant amount of time with caregivers other than parents, and despite the best parental intentions, they can get shuffled around from place to place while the ill sibling is in the hospital. Although parents may work diligently to attend to the needs of all their children, the parents are often overwhelmed and overburdened, and as a result the siblings of the diagnosed child often feel ignored and excluded, contributing to feelings of jealousy, guilt, anxiety, and sadness.[214,215] The type of challenges that are faced and how a sibling responds are greatly dependent on developmental level. For example preschoolers may experience significant anxiety related to prolonged separation from caregivers who remain at the hospital with the patient, whereas adolescents may be more concerned about details of their sibling's treatment and prognosis.

Siblings of children with cancer have been the subjects of numerous studies designed to investigate their adjustment and adaptation after the diagnosis of their brother or sister.[214,216-223] Findings suggest that most siblings experience some level of stress associated with the treatment of the ill child, especially in the first few months,[154,224] and that this stress may lead to deterioration in normal functioning. Siblings may demonstrate a range of externalizing and internalizing problems, including withdrawal from friends and activities, disturbances in eating and sleeping, temper tantrums, depressed mood, and anxiety.[219,220,225-229] A few studies have documented positive effects, particularly in older siblings, who may exhibit higher levels of empathy and maturity.[216,222,230-232]

Despite years of research highlighting the challenges encountered by siblings of children with cancer, relatively few targeted interventions have been developed for this group. A systematic review of the literature identified studies using individual intervention, camp, and group support to evaluate the impact on sibling psychological adjustment. Findings indicated that participation in interventions improved siblings' depressive symptoms, medical knowledge, and health-related quality of life.[233] Ideally interventions should address sibling adjustment throughout the treatment process rather than at specific phases (e.g., diagnosis or at the time of a bone marrow transplant).[234] General guidelines for improving sibling adjustment include involving the sibling in developmentally appropriate discussions as early as possible, educating the sibling about the illness and treatment course, encouraging the sibling to visit the hospital, and providing opportunities for supportive interactions (e.g., sibling support groups, individual counseling, and summer camp experiences).[215,235] Programs such as SuperSibs, a nonprofit organization for siblings of pediatric cancer patients,[236] provide opportunities for siblings to feel valued and heard through activities and services. Feelings of frustration, anger, jealousy, or guilt need to be acknowledged and normalized, and younger siblings may need to be reassured that the illness of their brother or sister was in no way attributable to anything they may have said or done. Having siblings maintain a routine by attending school or day care, socializing with friends, or engaging in various extracurricular activities provides structure and a sense of normalcy during a very challenging time for the family and increase the opportunities for social support when parents and caregivers are busy attending to the ill child. For siblings who demonstrate ongoing emotional distress or significant difficulties in returning to their regular school, family, and social routines, a consultation with a psychosocial provider should be recommended. Depending on the sibling's needs and available resources, they may be able to provide some short-term supportive therapy or make a referral to community or school-based resources.

Transitions and Changes in Care

While families transition from one phase of cancer care to another, they often experience the change as a loss. In each phase of treatment, children and families adapt, even unwittingly, to difficult circumstances of treatment, and when these circumstances change, they experience disruption in their new routines and habits. Parents may be particularly susceptible and often appreciate the irony of having spent days or week feeling "trapped" in the hospital, only to find themselves later terrified to leave it. Children may miss the special care they received in certain settings, the reassurance and attention they received from nursing staff, relationships they developed with other children, and the relaxed expectations that may apply when they are undergoing intensive treatment. Many kinds of transitions in care can be challenging to families, but discharges from the hospital and the transition from active treatment to going "off therapy" may be among the most stressful,[237-241] especially for parents. During these transitions it is especially important for providers to be sensitive to the likelihood that families will feel anxious and unsure, even while the treatment is "progressing." Providers may naturally tend to emphasize only the positive aspects of a transition, but this approach is likely to increase feelings of anxiety and isolation. Providers should normalize families' feelings by asking about their uncertainty or ambivalence with regard to moving to a new phase of treatment and should reassure them that these reactions are common. Asking, "How does it feel now that you are getting ready to go home?" is much more useful to the family than a well-intentioned statement of "Oh, you must be so happy to be going home." Acknowledging that a transition may require the patient and family to adapt to new routines and providers or manage aspects of the medical care more independently is important, as is reassuring the family that there will be continued support for them during the transition period.

For families beginning a new phase of treatment, such as outpatient radiation or chemotherapy, a tour of the new treatment area, introductions to new providers, and opportunities to meet other children and families can be very helpful. Child life specialists can be particularly helpful to children acclimating to new treatment settings and modalities. Families transitioning from active therapy to off-treatment care can experience significant uncertainty and emotional distress, especially when treatment has lasted for a year or longer. Although some families find the end of therapy a great relief, many families are surprised to find themselves experiencing anxiety, uncertainty, and feelings of helplessness reminiscent of feelings they had during the crisis period of diagnosis.[238] For these families it is helpful to normalize their reactions, helping them to understand that during active therapy their anxiety was kept at bay by the demands of treatment, the frequent contact with providers, and the rituals of medical care. While the demands of treatment decrease, they may find themselves looking back and reflecting on all they have been through since diagnosis. In addition the cessation of treatment raises concerns about the possibility of relapse, and less frequent visits to the oncologist may make parents in particular worry about how their child's health will be monitored. Because the off-therapy transitions can be a time of increased stress and uncertainty for many families, it is helpful to anticipate these needs by offering additional psychosocial support either in individual meetings with families or through parent support groups. In addition to providing increased emotional support, programs providing tailored medical information for families ending treatment, such as a summary of the child's treatment and their schedule for off-treatment and follow-up care, can be effective for reducing anxiety and uncertainty.[238]

Home Care

Children's cancer treatment will often require that some specialized care be provided in the home. Depending on the specifics of the child's treatment, specialized care may include taking oral medications or nutritional supplements, caring for a CVL, or receiving injections or intravenous medications. Care in the home setting is critical to allowing children and families to leave the medical setting and return home to normal routines, but it also represents a significant new responsibility for parents and children.[242,243] Over time, providing care in the home can give both parents and patients a way to feel active and competent in managing their own care, but at least initially it can be a source of burden and anxiety. Parents may feel overwhelmed both by the technical aspects of home care they must learn to provide, such as flushing a CVL or giving an injection, as well as by the sense of responsibility for monitoring their child's health. Children can feel confused about why their home setting is being "invaded" by the medical world they had hoped to leave behind in the hospital, and some resistance to treatment may emerge. Receiving care from the parent rather than a medical provider can be a relief for some children but may raise problems for other children. Parents' discomfort or unfamiliarity can be unsettling for children, and the parent as medical provider can be an awkward change of roles in the family. Young children may experience difficulty in having parents shift from an emotionally supportive role to being the hands-on person providing their care, and thus they may become resistant to certain aspects of their care, such as taking oral medications. Older children and adolescents may want to assert their independence and be directly involved in their care but may not know how to do so. They may also be ambivalent, with some adolescents alternately striving for independence and exhibiting dependence and passivity.

Practical education from nursing staff is vital for parents and children assuming responsibility for home care.[242,244] The availability of home care nurses to provide some of this care, monitoring, and education is also critical. Nursing and psychosocial professionals can also offer important emotional support by normalizing feelings of uncertainty and responsibility and by promoting the development of a sense of competence by patients and families. For children of all ages it is useful for parents and providers to consider how the child can be involved in his or her care in a way that will help the child feel some mastery and sense of control. If problems with a child's compliance are anticipated or develop at home, the psychosocial care provider should work with the family to develop a behavioral plan to address the problems. Supporting the parents in their role, helping them to set clear and consistent expectations, implementing a reward system with tokens, and helping the child find a way to be appropriately active in his or her care can all be useful interventions. With older children and adolescents, a token reward system such as a sticker chart is less likely to be effective, and some negotiation of roles and responsibilities will often be more helpful. Family members may need to be encouraged to be more flexible and try involving different family members or different schedules to manage their home care. In these cases the psychosocial care provider may want to involve other members of the treatment team such as nurses, nutritionists, or pharmacists in considering how the home care plan can be adapted for the needs of a particular family. Peer support from other families and patients may also be helpful.

SPECIAL ISSUES THAT MAY ARISE DURING TREATMENT

Marital Adjustment

A pediatric cancer diagnosis has immediate and significant consequences for those connected to the ill child, most notably the parents. Although the level of care a child will require through the treatment process will depend on several factors, including the severity of illness and the child's developmental level, most children undergoing cancer treatment will require significant support from at least one parent or caregiver. Many families find that managing the child's hospitalizations, clinic visits, daily medications, adverse effects of treatment, and other illness-related factors is a full-time job, often leaving the responsible adult feeling overwhelmed. With one parent now dedicated to caring for the ill child, the other parent is often left to support the family financially, attend to other children, and ensure that the household continues to function effectively. Not surprisingly these circumstances can present significant challenges to all aspects of family functioning and can test the marital relationship. Understanding how these circumstances affect the child and family is complex and necessitates the consideration of several factors, such as parental coping, family cohesion and organization, emotional expression, and marital satisfaction.[245]

Given the challenges that parents must face after their child has been diagnosed, one might predict that marital relationships would suffer as a result. Research has suggested that although parents of children with cancer were no more likely to divorce than other parents and that marriages generally remain stable,[246-248] marital dissatisfaction and distress do increase.[249-251] Specifically Hoekstra-Weebers and colleagues[249] noted that marital dissatisfaction was associated with higher levels of psychological distress 6 and 12 months after diagnosis, but not at the time of diagnosis. Schuler and colleagues[250] found that parents, especially mothers, experienced distress with regard to adjusting to new demands. Similarly Dahlquist and colleagues[94,251] reported that marital distress was predicted by general emotional distress and a discrepancy between the couple's perceived anxiety levels. Although pediatric cancer may strain marital relationships and accentuate differences in parental coping styles, these results suggest that couples are committed to remaining in their marriages, perhaps to minimize any additional disruption to the family and to the diagnosed child. Given that marital distress appears to increase over the course of the child's treatment and may not be evident at diagnosis when clinical assessments are initiated, it may be helpful for medical staff to monitor parental functioning over time and to seek consultation from mental health colleagues when marital tension is evident and could potentially affect the adjustment of the child and family.

Nonadherence

The ability to adhere to treatment regimens is an important clinical issue that has ramifications for overall disease outcome and clinical trial data.[252] In pediatric oncology, nonadherence can be used to refer to failure to attend medical appointments, undergo chemotherapy or take other medications as directed, and comply with clinical research requirements.[253] Nonadherence can have significant implications such as inaccurate conclusions regarding medication efficacy, skewed research findings for experimental protocols, and even a decreased chance for survival.[254] In one study nonadherence with oral cancer treatment was found in nearly 60% of adolescents and 33% of children younger than 13 years.[255]

The adherence literature has consistently demonstrated that adolescents are at greater risk for nonadherence compared with younger or older patients.[254,256-258] The nonadherence rates for adolescents receiving cancer treatment are consistent with findings of nonadherence in other chronic diseases such as cystic fibrosis[259] and diabetes.[260] The nonadherence demonstrated in the literature is likely related to the developmental tasks associated with adolescence. On a practical level, because adolescents spend more time away from their parents, the parents (especially those who are working or caring for other children) may naturally expect the adolescent to remember when to take medications and to take them more independently. Psychologically adolescents naturally develop an increased sense of autonomy and move away from being dependent on parents, which may make it more complicated to negotiate how their medication use will be monitored.[147] Although most parents and adolescents may fully intend to adhere to medication schedules, the combination of the adolescent's need to exert some level of independent functioning, the need to fully integrate adolescents into school and social settings where parents may have less opportunity for oversight, and multiple demands on parents can increase noncompliance and create opportunities for miscommunication and conflict with regard to who is responsible for ensuring adherence to treatment.[252]

Despite the belief of adolescents that they can take care of themselves, they face a number of challenges in adhering to a complicated oral treatment regimen. Their neurocognitive abilities may not be appropriately developed, and executive functioning challenges may interfere with their capacity to organize medication schedules. In addition many adolescents may not adhere to treatment recommendations if the treatment schedule or medication adverse effects interfere with pleasurable activities. Psychosocial care providers can be helpful in terms of potentially preventing adherence issues by encouraging parents and providers to include adolescents, when developmentally appropriate, more fully in their medical care. Simply raising the issue can be valuable, because letting families know that trouble with ongoing adherence to medication is not unusual can help many parents and patients acknowledge the issue and talk more openly about it. Research has demonstrated that including adolescents in the treatment decision-making process increases their sense of autonomy and improves treatment adherence.[257] In addition, working with the medical providers to factor in flexibility, when appropriate, to accommodate the social needs of adolescent patients may help increase adherence.

A number of individual, family, and treatment characteristics have been linked to treatment adherence. Die-Trill and Stuber[255] found that characteristics of the child such as behavioral problems, poor self-image, poor insight regarding prognosis, and poor coping mechanisms were positively correlated with nonadherence. Family predictors of nonadherence included parental depression and an increase in the number of siblings. Treatment intensity and the number of medications needed for effective treatment also increase nonadherence. Die-Trill and Stuber[255] identified additional factors that promote treatment adherence, including increased anxiety in female patients and increased obsessive-compulsive behaviors in parents of male patients.

Recent research on adherence has begun to utilize advances in technology to move beyond self-report and pill counting to incorporate electronic monitoring devices on pill bottles and blood work. In one such study Bhatia and colleagues[254] identified nonadherence in 44% of children with acute lymphoblastic leukemia and found that 59% of the relapses were related to nonadherence to medication regimens. In addition ethnic differences in adherence were reported, with Hispanic patients having significantly higher rates of nonadherence when compared with other ethnic groups. Patients from single-parent homes were also at greater risk for nonadherence. It is likely that in such households, adolescents are more likely to be responsible for medications, and given the issues previously raised, they have difficulty adhering to the recommended medical treatment.

Although a significant amount of literature has been devoted to nonadherence in adolescent patients, issues associated with adherence can also be a result of parent error. Protocols that involve oral regimens have increased, subsequently requiring parents to be responsible for appropriate dosing and administration. A multisite study of medication errors in the home revealed that one in two patients were exposed to at least one, if not more than one, medication error when medications were administered in the home. These errors mostly entailed inaccurate dosing or missed doses.[261] It is important that the medical team consistently monitor patients and parents regarding the use of oral medications, and if nonadherence or errors are suspected, education and training should be provided to support families in adhering to what can often be complicated treatment regimens.

Given that adherence is essential for the safe and successful treatment of pediatric cancer, a number of interventions can be incorporated to increase adherence, such as educating parents and patients about the prescribed medical treatment and the medical ramifications of not taking medications as recommended. It is also important to understand the neurocognitive capabilities of patients and families and factor that knowledge into helpful strategies that can be used to aid organizational and memory issues, thus helping parents to develop supportive relationships with their children that will allow the use of appropriate behavioral techniques.

Depression and Anxiety

Given the many challenges that children and adolescents face during the course of cancer treatment, many investigators have hypothesized that children with cancer are at risk for higher levels of depression and anxiety. Research findings to date are mixed, with some studies suggesting emotional and behavioral maladjustment, including depression and anxiety, in children with cancer[262-264] and other studies showing less behavioral or emotional disruption in these children.[265,266] Social support and effective parenting throughout treatment appear to provide protection from the adversity encountered by the child with cancer[266] and may be important buffers against serious psychological distress in patients.

Given the stress associated with the diagnosis and treatment of pediatric cancer, some level of heightened anxiety and depression is to be expected, although these symptoms may not be of sufficient intensity to reach clinical significance and may not be consistent with a psychiatric diagnosis. The inability to attend school, participate in extracurricular activities, and socialize with friends, coupled with invasive procedures, nausea, and hair loss, would leave even the most well-adjusted child or adolescent struggling to maintain appropriate functioning. Given the likelihood that most patients will experience at least some transient symptoms of anxiety and depression, the tasks for providers and parents is to identify these symptoms, assess their level of intensity and functional significance, and plan for appropriate interventions to address them.

The medical team, with the assistance of parents or caregivers, should consistently assess the child's mood and behavior for signs of emotional difficulty, comparing current functioning with functioning prior to diagnosis. The team may ask why a child is no longer playing his or her favorite video games, being disrespectful toward nursing staff, refusing physical therapy, or ignoring visitors. Anhedonia, sleep disturbance, irritability, and social isolation are some of the signs and symptoms of depression that are commonly seen in children and adolescents coping with cancer treatment. For most patients these symptoms will be mild to moderate in severity and can be thought of as reflecting expectable reactions to the illness and demands of treatment. Supportive care provided by nurses, parents, and child life specialists to minimize physical discomfort, empathize with the frustrations and disappointments of being a patient, and promote opportunities to find some pleasurable activities can be useful for most of these individuals. Similarly nightmares, heightened reactivity, and worry about future health problems or medical procedures are indicators of anxiety commonly encountered in children with cancer. Parents and providers can often help patients with these symptoms by providing reassurance, offering information about the medical course, providing the opportunity to express their worry openly, and teaching some relaxation and distraction techniques.

When symptoms of depression or anxiety do not respond to routine supportive care, cause significant distress, or otherwise interfere with the child's ability to engage in essential daily activities or comply with medical care, a specialized mental health evaluation should be sought. This evaluation drawing on information from the patient, family, and medical team, should be focused on determining the extent and severity of behavioral and psychological symptoms, the relevant psychiatric disorders, if any, as well as deficits in knowledge or coping skills that may need to be addressed. Based on this information, the mental health specialist should be able to recommend which of a variety of types of interventions such as cognitive-behavioral therapy, expressive therapy, play therapy, psychopharmacology, or family therapy would be most appropriate. Psychological assessment can be complicated by questions of whether a pediatric patient's physical symptoms are secondary to the physical cancer or are evidence of psychological disturbance.[267-269] The physical effects of treatment and adverse effects of medications may mimic symptoms of depression or anxiety and interfere with an accurate diagnosis. While working to understand how medical factors can contribute to the presentation of psychological symptoms, it is important not to dismiss these symptoms too quickly as manifestations of physical illness. Hedstrom and colleagues[270] found that medical and nursing staff underestimate the level of depression and anxiety in adolescents with cancer, underscoring the need to carefully consider depression and anxiety as problems in this group.

Relapse and Recurrence

Patients and families who experience a relapse or recurrence of cancer can be expected to enter a second crisis period. Similar to the initial crisis of diagnosis, families experience a cognitive and emotional overload; they often are overwhelmed with fear and anxiety at the same time they are trying to understand the medical implications of the return of the cancer. Families typically feel shocked by news of a relapse. For many families, faith in their medical care, trust in the world, and hope for future treatment are severely challenged.

The initial approach to this new crisis should draw on the elements of psychosocial support described in the section on the crisis of diagnosis, including provision of psychosocial support and participation in a new treatment conference or "day one talk." In the context of a relapse, emotional distress and disbelief are to be expected, and parents, older patients, and siblings may be distraught. Presenting information about prognosis after relapse can be even more difficult, because the prognosis is typically less favorable, and patients and families who previously may have been reassured may now need to be told that cure is less likely or even not to be expected. Families need to have accurate medical information presented to them in a way they can understand, but perhaps just as important, they need to feel that the physicians and other providers are committed to continuing to care for them. For some patients and families a recurrence may be experienced as a personal failure, and the team should be careful to readdress this issue of blame and causality in the context of relapse or recurrence. In cases in which a new treatment plan means transferring care to a new clinical service (e.g., as in the case of a bone marrow transplant) or referral to a new care team or hospital, great care should be taken to ensure that patients and families do not feel abandoned.

The psychosocial challenges facing the patient and family after relapse depend to a large extent on the subsequent treatment that is planned and the extent to which cure remains the goal of treatment. When potentially curative treatment is planned, patients face the challenge of reengaging in a new and potentially more intensive therapy regimen. Patients and families already burdened by an initial treatment may have more trouble adjusting to new demands along with increased anxiety and the psychological experience of "starting over" with a new treatment. Psychosocial care providers should be prepared to reassess the patient and family in this new context and offer emotional support and crisis intervention. Psychosocial providers should also anticipate new issues that could emerge such as financial stress, parent depression, patient behavioral problems, or emotional distress and be prepared to help the family address these issues.

For some patients the likelihood of cure after relapse or recurrence is remote. For these patients, treatment options may include palliative care or experimental therapies. Learning that a cure for the cancer is unlikely and that the patient may be expected to die of his or her disease is devastating for the family. Parents and patients are likely to be terrified and overwhelmed, and care providers may feel unsure about how to help these families. Communication between the physicians and other members of the team is especially important at this juncture,[80] and care should be taken to communicate directly to patients as well as parents and to provide honest information in a sensitive manner. Psychosocial providers should participate in team meetings with the family, assess the needs of the patient, parents, and other family members, and offer crisis intervention and emotional support. They should anticipate that symptoms of depression, hopelessness, and anxiety may become significant in one or more family members and be prepared to offer clinical care and/or referrals to other specialists or community agencies. A more comprehensive discussion of care for the dying child is included in Chapter 70.

SPECIAL POPULATIONS

Adolescents

Adolescence is traditionally seen as a time of transition and growing independence. The diagnosis of cancer during this developmental stage has the potential to disrupt normal functioning and limit the attainment of specific goals that move the adolescent from childhood into adulthood. Research has considered several important areas related to the psychosocial adjustment of adolescents with cancer, including family factors, psychological factors, and socialization factors.[26,209]

Mental health professionals have noted that children and adolescents often function as well or as poorly as their parents during stressful life events. The psychological adjustment of adolescents with cancer was noted to be better when maternal distress was low[271] and maternal adjustment was high.[272] In addition adolescents benefited from the ability of family members to introduce a sense of normalcy and felt more supported during treatment when family members demonstrated flexibility.[148] Some adolescents noted that stressful family relationships impeded successful adjustment to the illness.[273] These data taken together suggest that the adolescent's family is crucial to the adolescent's successful coping and illness management. The medical team should encourage open communication between family members that will promote positive interactions and allow for the ongoing assessment of individual functioning. Psychosocial support should extend beyond the adolescent patient to all family members to ensure the healthy functioning of the entire family system. When problems in an adolescent's behavior or coping are identified, providers should be mindful that some family-focused assessment and intervention may be indicated.

Psychologically adolescents typically possess cognitive abilities that allow for a more sophisticated understanding of their illness and treatment than would be found with younger children. Adolescents often seek information[102,126] and feel empowered by their understanding, which may in turn facilitate their active participation in treatment decisions, thereby increasing their use of effective coping strategies and their overall sense of control.[25] However the ability to understand illness-related information does not guarantee increased psychological adjustment. In fact some adolescents may feel overwhelmed by extensive medical information and corresponding treatment decisions, increasing the level of stress and potential psychological maladjustment. To ensure that the adolescent is appropriately informed, a careful assessment must be conducted to evaluate how information is processed and understood by the adolescent and what amount and type of information will be most helpful. Because adolescents may feel that opportunities to achieve increased independence (e.g., attaining a driver's license) are limited as a result of their illness, including the adolescent in treatment discussions, facilitating effective coping strategies, and encouraging participation in the decision-making process may promote an increased sense of autonomy.[274]

Socially the adolescent's ability to engage with peers, participate in extracurricular activities, or attend school while undergoing treatment is often very limited. Immediately after diagnosis, extensive support is often available to the adolescent and the adolescent's family. However, as treatment progresses and the initial shock associated with the diagnosis decreases, support from friends, teachers, and others in the community may be less consistent. With time friends may return their focus to school and other activities, leaving the diagnosed adolescent feeling isolated and left out.[126,175,209,275] Evan and Zeltzer[25] suggest that developmental level plays a significant role in the type of support that an adolescent both provides and seeks. Encouraging flexibility and support with regard to an adolescent's participation in his or her usual activities, such as attending school, attending social events, and spending time with friends, can help adolescents feel "normal" and may increase adherence to treatment.[253] Encouraging the adolescent patient to bring a friend to a clinic appointment can also be helpful to bridge the divide between peers and the medical setting for some adolescents. Research findings suggest that adolescents with cancer seek social support from same-aged peers encountering similar developmental issues[276] and from parents and other adults who have a wider range of life experiences that may be relevant to overcoming their illness.[275]

Studies have considered several factors related to the development of successful adolescent social relationships, including the importance of self-esteem and sexual identity.[26,277-282] For example, findings suggest that adolescents who are absent from school may begin to experience academic difficulties that have a negative impact on their self-confidence and self-esteem. This decrease in self-confidence and self-esteem undermines the adolescent's attempt to form and sustain social relationships. Other findings highlight sexual identity and the significant role that sexual identity plays in adolescent relationships and developing self-esteem.[26] The adolescent diagnosed with cancer may have a negative body image as a result of treatment-related adverse effects (e.g., hair loss, procedural/surgical scars, and weight gain or loss)[283-286] and more limited opportunities for both formal and informal sex education, impeding healthy sexual development and positive self-esteem.[287] Evan and colleagues[26] suggest assessing the adolescent's cognitive, social, developmental, and family functioning, both to determine the most appropriate ways to enhance sexual health and self-esteem and to recommend opportunities to assume personal control and interact with other adolescents who may be encountering similar experiences.

Social support and social relationships are essential to successful adjustment during the treatment course and beyond. Although parents and other family members typically provide the primary, day-to-day support needed by the adolescent patient to successfully complete treatment, peer relationships are equally valuable, because they allow adolescents to remain connected to other key aspects of their life that exist outside of their treatment. Members of the medical staff can also provide important interpersonal connections that can greatly improve the adolescent's social functioning. The medical team should work to understand how cancer is adversely affecting the adolescent's peer relationships and encourage peer interactions by supporting the adolescent's return to school and participation in peer-related activities when feasible. For adolescents who have been dating, cancer often interferes with their ability to develop these relationships or to maintain contact with a boyfriend or girlfriend. For the sexually active adolescent, the illness may also raise questions about whether they need to limit their sexual activities because of treatments or risks for infection. Counseling and information on contraception and prevention of sexually transmitted diseases should be provided to sexually active adolescents in keeping with recommended practices for this age group.[288,289] Because parents may not be privy to all of their adolescent child's romantic or sexual activities, it is important that providers discuss these issues with adolescents in private and provide appropriate support and information.

Neurooncology

The literature has indicated that, in general, children and adolescents treated for cancer will have a positive adjustment to treatment and that once the acute crisis of diagnosis has passed, they tend to adapt positively.[290,291] The diagnosis of a pediatric brain tumor is often more complicated given the location of the tumor, the toxicities of treatment, the possibility of long-term medical late effects, and the poor prognosis associated with many pediatric brain tumors.[292,293] Research has often indicated that patients diagnosed with central nervous system (CNS) tumors are at greater risk for psychological difficulties, neurocognitive deficits, poor functional outcomes, and decreased quality of life when compared with children treated for other cancers.[174,290,294-298] In addition disease-related fear, uncertainty, loss of control, and depression have been found to be heightened among parents of children treated for a CNS tumor when compared with parents of children who have acute lymphoblastic leukemia or acute myeloid leukemia.[294] Issues associated with diagnosis, the impact of treatment on immediate and long-term functioning, and the morbidity associated with CNS tumors are factors contributing to the increased risk for psychological distress among parents.

The terms "benign" and "malignant" are often the nomenclature by which we understand the gravity of a particular diagnosis. However in pediatric neurooncology, very little is benign. Children and adolescents die of both benign and malignant tumors. Regardless of the label, persons with both benign and malignant tumors require treatment (e.g., surgery, chemotherapy, radiation, or autologous stem-cell transplant) that comes with significant demands that can be challenging for patients and families. Parents are often in the position of consenting to a treatment that will cause significant late effects and will have a negative impact on quality of life for their child, all in the hope for a cure. The stress associated with making this decision in the context of trying to integrate new diagnostic information, the input of family and friends, and the abundance of material on the Internet can be extremely overwhelming for parents. Many families opt to seek second opinions at other institutions, which can be helpful but also can make treatment decisions more complex. Psychosocial care providers can help parents process information, encourage additional conversations with medical providers, and facilitate coping styles that most effectively support decision making.

Given that the cancer is located in the brain, all treatment interventions come with a number of risks. An insult to the brain can have an impact on motor skills, cognition, vision, speech/language, and emotional regulation. Although some of the postoperative complications can improve, it is also possible that a patient may not return to his or her presurgical level of functioning,[299] which has significant implications for self-esteem and self-identity. Psychosocial providers working with children with brain tumors need to recognize the impact of loss, grieving related to permanent changes in functioning, despair pertaining to the need for extensive rehabilitation, and uncertainty about the future. These issues are prevalent not just for the patient but for the family as a whole. Providing the space in which a patient and family can grieve, while dealing with ongoing medical stressors, is important for future psychological adjustment. Patients may believe that they are unable to engage with peers because of their limitations; however, guidance about how to encourage participation in activities is crucial. For patients who may not be able to engage in athletics, ongoing participation on the sports team through a team manager position or scorekeeper can be instrumental in keeping patients connected to peers, bolstering self-confidence, and fostering the attainment of developmental milestones.

Although significant improvements have occurred in the survival rate for some pediatric brain tumors, some diagnoses are still associated with a very poor prognosis. The medical team is often faced with the difficult task of telling a family that their child is not likely to survive, while preserving some hope through the form of treatment options. Psychosocial care providers can serve as an important support during the meeting, provide guidance with regard to having additional family members at the meeting, and validate the challenges of making treatment decisions. Because of advancements in treatment, parents are often faced with the challenge of deciding between clinical trials, none of which has data regarding efficacy. Parents are often overwhelmed at this time while they process the news of the diagnosis, the prognosis, and the treatment options. It is crucial that psychosocial clinicians assess the parents' psychological history and current functioning to identify interventions that are required immediately to help facilitate decision making and treatments that will provide symptom relief on a long-term basis.

Hematopoietic Stem Cell Transplant

Similar to patients with CNS tumors, patients and families for whom stem-cell transplant is the recommended treatment are at increased risk for psychosocial complications during and after treatment in terms of their overall psychological adjustment.[300,301] Increased vulnerability to psychological distress and the posttraumatic symptoms described in the literature that are associated with the stem-cell transplant experience can be attributed to factors associated with treatment risks, morbidity, the stress associated with simply trying to get to the point of transplantation, restrictions and isolation, and the late effects associated with treatment.

The process of getting disease in remission or eliminating any residual disease can be an anxiety-provoking start to the challenges of transplantation. Patients and families often experience anticipatory anxiety as they await news from screening tests that will clear the patient to move forward with the transplant process. At the same time, significant stress is associated with finding an appropriate donor. Many patients have siblings who are eligible to be the donor, and although they are certainly fortunate in terms of having a good match, this process becomes complicated and plays into multiple layers of family dynamics. Sibling donors have been shown to be at risk for posttraumatic stress disorder, anxiety, and low self-esteem.[302-304] Psychosocial care providers play an important role by conducting donor evaluations that provide the medical information donors need to ensure that they understand the process. Psychosocial care providers also provide the psychological support and care required to ensure that the donor is not being coerced into the procedure and understands the possibility of both a positive and negative outcome and that neither outcome is associated with the donor process. Parents now have to worry about the emotional and medical functioning of both the sibling and the patient, leading to increased vulnerability for distress.[305]

Parents with a child who requires a bone marrow transplant are in the position of choosing a treatment that will irrevocably change the course of their child's life because of the toxicities of treatment. The adverse effects of transplantation can include hearing loss, infertility, renal failure, cardiac dysfunction, growth and gonadal failure, secondary malignancies, neurocognitive delay, and possible death. Discussion of the potential risk of death is part of the consenting process and indicates the intensity of the treatment and the potential psychological trauma that can result for both patients and parents. Indeed retrospective studies have indicated that parental distress tends to be at its highest before the actual transplant procedure.[306,307] This information is crucial in terms of determining points of intervention, given that the literature has shown that fewer maternal depression symptoms are associated with improved patient outcomes after the transplant procedure.[308] Ensuring that patients and families have been provided with appropriate medical information up front and ample opportunity to ask questions of the medical team is one way that psychosocial care providers can help empower families before the transplant procedure.[309] A thorough assessment that includes identification of significant parental psychological distress well before the start of transplant process is important to ensure that potential psychotropic interventions have ample opportunity to take effect before the patient enters the hospital.

Given the intensity of the treatment, the extended period of hospitalization, and the potential for significant medical complications, families should be followed closely by their psychosocial care provider throughout the transplant process. Use of cognitive-behavioral interventions such as relaxation strategies and guided imagery can be helpful for both patients and caregivers. Implementation of behavioral plans that provide positive reinforcement to the patient with regard to the significant demands of treatment can be very helpful. Given the significant stress associated with transplant procedure, as well as the isolation that can occur for caregivers, parent support groups can be extremely helpful in connecting parents with others going through similar experiences, allowing for parental self-care, and providing a forum for discussion of worries and challenges. Many medical institutions also incorporate family-centered rounds or regularly scheduled family meetings to keep lines of communication open, provide an opportunity for parents to ask questions of the team, and address any logistical or systemic issues that may be negatively affecting the family's adjustment to the transplant. Keeping in close contact with medical, nursing, and child life care providers is critical to providing the best care for these families who are at significant psychosocial risk.

Once patients have completed the transplant and are discharged from the hospital, they must participate in an intensive outpatient plan that can include multiple trips to the hospital or clinic per week, use of multiple medications, and restriction in terms of social contact. Given the immunocompromised status of patients after transplantation, they are not allowed to attend school or be in an enclosed space with a lot of people. This restriction can be extremely difficult for children and adolescents who can be essentially cut off from their peers. This period is also anxiety provoking because parents are concerned about the possibility of complications, infections, and the potential for disease relapse. Parents are often on high alert with increased vigilance regarding oral intake, participation in physical/occupational/speech therapies, and/or hygiene. Adolescent patients in particular may have significant difficulty in managing a hypervigilant parent in the context of their limited control. Power struggles between patients and parents are not uncommon, and anticipatory guidance with regard to these potential challenges early in the process with a focus on prevention can be an important role for the psychosocial clinician.

With the significant limitations placed on daily functioning as a result of the intensive treatment and the very real possibility of disease relapse despite the transplant, it is understandable that patients who have undergone bone marrow transplant are at increased risk for psychological distress, both acutely and long term.[301] Clinicians should be aware that subsets of patients are more likely to experience psychological difficulties, specifically patients who are dealing with debilitating adverse effects such as graft-versus-host disease (GVHD) and its treatment. Results from the Bone Marrow Transplant Survivor Study indicated that active chronic GVHD was associated with somatic and global psychological distress.[310] In addition, the use of corticosteroids in the management of GVHD is another factor associated with depression and diminished quality of life.[311]

Despite the risks, some reports in the literature demonstrate that many survivors of bone marrow transplant have a good health-related quality of life within 12 months after the transplant procedure, particularly if they are not affected by severe adverse effects of treatment.[300,312] Parents and children may have very different perspectives on the child's progress and adaptation after transplant, making it important to include both patient and parent perspectives whenever possible.[301,313,314] Parents may experience elevations in distress during the acute phase of the transplant process, but the distress typically resolves approximately 4 to 6 months after the transplant for most parents. Nonetheless subgroups of parents exhibit distress after the transplant that is significant enough to meet the criteria for posttraumatic stress disorder or to be classified as having posttraumatic stress symptoms; families with lower socioeconomic backgrounds have been noted to be at particular risk.[315] With this in mind, clinicians should incorporate assessment of social and psychological functioning of the patient and the family into the routine follow-up of patients undergoing a transplant. Informing patients and families that ongoing psychological or social problems are not uncommon after transplant may help families be forthcoming about their functioning and help those who have significant difficulties to accept a referral for more specialized assessment and treatment.

    This document was developed by the International Society of Paediatric Oncology Working Committee on Psychosocial Issues in Pediatric Oncology. It addresses the therapeutic alliance between families and staff and the overarching goal of curing cancer while minimizing medical and psychological toxicities.

58. Mack JW, Grier HE: The day one talk. *J Clin Oncol* 22:563–566, 2004.

    This article outlines a thoughtful and sensitive approach for physicians who need to inform the family of a child's cancer diagnosis. The article provides concrete suggestions for the content and structure of the "day one" talk, emphasizing an approach that is empathic and supportive to patients and families.

64. Levi RB, Marsick R, Drotar D, et al: Diagnosis, disclosure, and informed consent: learning from parents of children with cancer. *J Pediatr Hematol Oncol* 22:3–12, 2000.

    The authors report on a retrospective study of parental perception surrounding their child's cancer diagnosis and the process of informed consent. Focus groups were conducted and themes associated with receiving the diagnosis, how to improve the informed consent process, and lack of control were discussed. Limitations were identified in parental understanding of the distinction between the treatment, research participation, and other aspects of the cancer experience.

80. Mack JW, Wolfe J, Grier HE, et al: Communication about prognosis between parents and physicians of children with cancer: parent preferences and the impact of prognostic information. *J Clin Oncol* 24:5265–5270, 2006.

    The authors of this study examined parents' preferences for prognostic information in regard to their child's cancer diagnosis. Parents were surveyed and findings indicated that the majority of parents wanted as much prognostic information as possible and wanted that information to be in numbers. Although some parents found the information distressing, they were no less likely to want the information.

104. Dolgin MJ, Phipps S, Fairclough DL, et al: Trajectories of adjustment in mothers of children with newly diagnosed cancer: a natural history investigation. *J Pediatr Psychol* 32:771–782, 2007.

     This study assessed posttraumatic stress symptoms (PTSS) in mothers of children who were diagnosed with cancer, the relationships between sociodemographic and psychosocial distress over time, and whether particular subgroups of mothers could be identified based on trajectory of adjustment. Mothers completed standardized measures at the time of diagnosis, 3 months, and 6 months. Findings indicated mildly elevated negative affectivity and PTSS at the time of diagnosis, but improvement over time. The study was able to identify subgroups of mothers who were likely to have particularly trajectories of adjustment.

105. Kazak AE, Boeving CA, Alderfer MA, et al: Posttraumatic stress symptoms during treatment in parents of children with cancer. *J Clin Oncol* 23:7405–7410, 2005.

     This study examined posttraumatic stress symptoms (PTSS) in mothers and fathers of children receiving treatment for cancer and in relation to treatment variables. Parents completed questionnaires and data were obtained from oncologists regarding treatment intensity. With the exception of one parent, all participants reported PTSS. In families in which both parents participated in the study, 80% had at least one parent report moderate to severe

PTSS. Treatment-related variables were minimally associated with PTSS.

117. Chen E, Craske MG, Katz ER, et al: Pain-sensitive temperament: does it predict procedural distress and response to psychological treatment among children with cancer? *J Pediatr Psychol* 25:269–278, 2000.

This intervention study examined pain sensitivity and distress in children undergoing lumbar punctures (LPs). Baseline data were gathered on pain sensitivity, and then children were randomized into the psychological intervention arm or control group. Findings demonstrated that children who reported high pain sensitivity had higher levels of anxiety and pain prior to and during the LP. Children who had higher pain sensitivity and who received the intervention had significant decreases in distress with time, whereas children with high pain sensitivity who did not receive the intervention reported elevated LP distress with time.

130. Sourkes BM: *Armfuls of time: the psychological experience of the child with a life-threatening illness*, Pittsburgh, 1995, University of Pittsburgh Press.

This seminal work on the emotional experience of the ill child provides clinical material that highlights the value and importance of a multidisciplinary approach. Using play therapy vignettes and stories from patients and their families, a rich description is provided of the challenges faced when experiencing a life-threatening disease and the interventions that can provide support around the issues of diagnosis, treatment, and loss.

154. Houtzager BA, Oort FJ, Hoekstra-Weebers JE, et al: Coping and family functioning predict longitudinal psychological adaptation of siblings of childhood cancer patients. *J Pediatr Psychol* 29:591–605, 2004.

This study examined the relationships between coping and family functioning in siblings of children with cancer. Assessments were conducted at four time points across 2 years since the cancer diagnosis. Findings indicated that at initial assessment (1 month after the diagnosis), psychological adjustment was impaired, but that it normalized over time. Optimism and having the sibling involved were noted as protective factors. Sibling age, gender, and coping style were noted to help identify at-risk siblings.

172. Zebrack B, Bleyer A, Albritton K, et al: Assessing the health care needs of adolescent and young adult cancer patients and survivors. *Cancer* 107:2915–2923, 2006.

In response to the literature demonstrating that adolescent and young adult (AYA) patients have not had improvement in cancer outcomes compared with other populations, this study sought to identify the health and supportive care needs of AYA patients and survivors. Findings from surveys of medical providers and young adults survivors indicated agreement in a number of areas of importance across health care professionals and AYA survivors. However the importance of meeting same-aged peers with cancer was rated significantly higher for AYA survivors. This study identified areas in which resources could be useful in potentially changing the gap in cancer outcomes between the population as a whole and AYA patients.

174. Vannatta K, Gartstein MA, Short A, et al: A controlled study of peer relationships of children surviving brain tumors: teacher, peer, and self ratings. *J Pediatr Psychol* 23:279–287, 1998.

This original research evaluated the behavioral reputation and acceptance of pediatric brain tumor survivors. Children (ages 8 to 18 years) were compared with nonchronically ill peers and data were gathered from peers, teachers, and patients. In comparison with same-aged classmates, children diagnosed with brain tumors were reported to be more socially isolated and received fewer friendship nominations. Issues associated with fatigue and school absence were reported. This article represents the initial work that highlighted the significant social struggles experienced by pediatric brain tumor survivors.

198. Zeltzer LK, Dolgin MJ, LeBaron S, et al: A randomized, controlled study of behavioral intervention for chemotherapy distress in children with cancer. *Pediatrics* 88:34–42, 1991.

This article reports on a prospective trial comparing hypnotherapy for reduction of chemotherapy-related distress with distraction/relaxation therapy and an attention control condition. Hypnotherapy was found to be superior to other conditions, with the results discussed in the context of complex interactions between biologic and psychological factors contributing to nausea and related adverse effects of chemotherapy.

210. Zebrack BJ, Gurney JG, Oeffinger K, et al: Psychological outcomes in long-term survivors of childhood brain cancer: a report from the childhood cancer survivor study. *J Clin Oncol* 22:999–1006, 2004.

This study evaluated the psychological outcomes of the pediatric neurooncology participants in the Childhood Cancer Survivor Study. Data for survivors and siblings were utilized and levels of psychological distress were consistent with reports in the general population. Survivors reported high levels of distress and depressive symptoms compared with siblings. Higher distress was associated with female gender, low household income, lower educational attainment, unemployment, poor health, and not being married. This study indicates that although treatment for pediatric brain tumors may not be associated with higher distress than the general population, the social difficulties experienced by survivors may be what puts them at greater risk for psychological challenges.

215. Spinetta JJ, Jankovic M, Eden T, et al: Guidelines for assistance to siblings of children with cancer: report of the SIOP Working Committee on Psychosocial Issues in Pediatric Oncology. *Med Pediatr Oncol* 33:395–398, 1999.

This document establishes a framework for the psychosocial care of siblings in pediatric oncology as developed by the International Society of Paediatric Oncology Working Committee on Psychosocial Issues in Pediatric Oncology, instituted in 1991. It outlines the general principles for helping siblings throughout various phases of treatment, including relapse, palliation, and death.

216. Sloper P: Predictors of distress in parents of children with cancer: a prospective study. *J Pediatr Psychol* 25:79–91, 2000.

This study investigated parental psychological distress in both mothers and fathers of children with cancer at 6 and 18 months after diagnosis. Relationships between illness, illness appraisal, resources, and coping were examined. Findings demonstrated elevated levels of distress for both mothers and fathers that were consistent with time. Internal factors such as appraisal and coping were associated with maternal distress, whereas external factors such as employment issues and the number of hospital admissions were associated with paternal distress. This article highlights the importance of identifying at-risk parents so appropriate supports can be put into place early during the treatment process.

253. Butow P, Palmer S, Pai A, et al: Review of adherence-related issues in adolescents and young adults with cancer. *J Clin Oncol* 28:4800–4809, 2010.

This review article examines studies that investigated medication adherence in the adolescent and young adult (AYA) oncology population between the years 1980–2008. Lack of adherence has been associated with higher risk of relapse, more adverse effects, and poor outcomes. The review highlighted the methodologic issues found in the AYA adherence literature, including a lack of clarity around defining the AYA age range and a lack of representation of oncologic diagnoses beyond leukemia and lymphoma. Reported rates of nonadherence range are broad, from 27% to 60%. Consistent predictors of adherence include openness of family relationships and support.

254. Bhatia S, Landier W, Shangguan M, et al: Nonadherence to oral mercaptopurine and risk of relapse in Hispanic and non-Hispanic white children with acute lymphoblastic leukemia: a report from the Children's Oncology Group. *J Clin Oncol* 30:2094–2101, 2012.

This original research report describes a prospective study of the prevalence and impact of nonadherence with oral mercaptopurine in a cohort of 327 patients treated for acute lymphoblastic leukemia. Using a medication event-monitoring system, findings show that nonadherence is associated with relapse of disease, ethnicity, and patient age.

283. Pendley JS, Dahlquist LM, Dreyer Z: Body image and psychosocial adjustment in adolescent cancer survivors. *J Pediatr Psychol* 22:29–43, 1997.

This study evaluated body image and social adjustment in adolescent cancer survivors and healthy peers. Participants completed questionnaires and a videotaped interview. Raters who were blind to medical history rated the attractiveness of the participants.

Survivors reported being less involved in social activities compared with the comparison group. Survivors who had been off treatment for a longer period reported lower self-worth, higher social anxiety, and more negative body image. Despite the self-report around these difficulties, these long-term survivors were not rated as less attractive by observers. This article provides evidence that psychological adjustment issues and body image difficulties may not fully emerge until well after treatment completion.

290. Zeltzer LK, Recklitis C, Buchbinder D, et al: Psychological status in childhood cancer survivors: a report from the Childhood Cancer Survivor Study. *J Clin Oncol* 27:2396–2404, 2009.

This article reviews findings from the Childhood Cancer Survivor Study regarding psychosocial adjustment, health-related quality of life (HRQOL), and life satisfaction. Comparisons are made between siblings and survivors and to normative data when available. Overall most survivors are psychologically healthy and report satisfaction with their lives; a significant proportion of survivors report more symptoms of psychological distress and poorer physical HRQOL. Risk factors for psychological distress and poor HRQOL are brain tumor diagnosis, female sex, lower educational attainment, unmarried status, presence of a major medical condition, and treatment with cranial radiation and/or surgery. Psychological distress also predicted poor health behaviors, including smoking, alcohol use, fatigue, and altered sleep.

310. Sun CL, Francisco L, Baker KS, et al: Adverse psychological outcomes in long-term survivors of hematopoietic cell transplantation: a report from the Bone Marrow Transplant Survivor Study (BMTSS). *Blood* 118:4723–4731, 2011.

The authors report on a large cohort study of survivors of hematopoietic cell transplantation. Psychological outcomes were assessed in bone marrow transplant (BMT) survivors and sibling control subjects. Survivors of BMT reported significantly higher levels of psychological distress than did their siblings, with those who had been exposed to prednisone reporting global distress across somatization, anxiety, and depression scales. High levels of somatization were reported, particularly for patients with graft-versus-host disease.

312. Parsons SK, Phipps S, Sung L, et al: NCI, NHLBI/PBMTC First International Conference on Late Effects after Pediatric Hematopoietic Cell Transplantation: health-related quality of life, functional, and neurocognitive outcomes. *Biol Blood Marrow Transplant* 18:162–171, 2012.

The authors of this article review the late effects in survivors of pediatric hematopoietic stem cell transplantation in the domains of health-related quality of life, physical function, and neurocognitive function.

314. Jobe-Shields L, Alderfer MA, Barrera M, et al: Parental depression and family environment predict distress in children before stem cell transplantation. *J Dev Behav Pediatr* 30:140–146, 2009.

This study examined the factors of parental and family environment variables in relation to the severity of distress in children slated to receive a stem cell/bone marrow transplant. Parental depression, family cohesion, and expressiveness were found to predict child distress, and parental depression, when high, was associated with elevated child distress regardless of family environment. This study provides evidence that parental psychological functioning prior to transplant is a predictor of child psychological adjustment.

CONCLUSION

Ethical decision making is a fundamental goal common to both clinical medicine and clinical research trials of all types. Broad attempts have long been made to thoroughly explicate the elements of ethical decision making that are common to both settings. However this goal has been pursued with increased vigor since the exposure of human moral abuses in the United States Public Health Service–sponsored Tuskegee Syphilis Study and by the Nuremberg trials and President Clinton's Advisory Committee on Human Radiation Experiments. The practical yield has been the production of highly influential documents such as the Belmont Report, the Declaration of Helsinki and its several versions, guidelines produced for the International Arena by the Council for International Organizations of Medical Sciences, and most recently, the adoption of the Universal Declaration of Bioethics and Human Rights in October 2005 by the United Nations Educational, Scientific, and Cultural Organization. Common to these efforts are principles such as respect for persons, beneficence, and justice. Table 74-1 lists selected guidelines for research ethics. But how do general principles translate into practical action that is ethically sound for the practitioner faced with a particular clinical situation, for the clinical research physician considering whether to offer a phase I trial to a patient, and for the investigator whose nontherapeutic trials pose some risks?

The issues become considerably more complex when the patient or research participant is a child and the decision maker is not the person facing the possibility of risk or benefit. This issue poses special challenges in both pediatric clinical medicine and pediatric clinical research. The challenges are made more acute by the fact that they are not static. The considerations change as a child grows in age and experience and as we move from standard-of-care therapy to clinical trials, which, as recently argued, involve the standard of care for future children, the results of which have been a remarkable success story.[1,2,3] Indeed it may be that survival percentages for adolescents and young adults with "pediatric" cancers have lagged behind those of younger patients in part because of their lower rates of participation in clinical trials.[4] Further the issues do not remain static across all types of clinical trials.[5] A child enrolled in a phase III clinical trial for newly diagnosed, standard-risk leukemia faces a situation very different from that of a child who has had multiple relapses of leukemia and whose family must choose between a phase I trial and a Make-A-Wish trip to the Grand Canyon.

This chapter begins with a brief historic review of the unique issues in pediatric medicine and pediatric clinical trials. It then moves to issues of parental permission and assent—issues that draw on, but are not fully informed by, the many studies of informed consent in adults. The differences in language and approach required as patients progress from phase III trials to phase I trials and palliative care are examined. After these more general issues, we will consider more specific questions, such as those raised by autopsy, stem cell transplantation, advances in

technology, conflict of interest, insurance, ethics consultation, and international bioethics.

HISTORIC PERSPECTIVE

For hundreds of years, medical research has involved children as subjects.[6] Edward Jenner first used an experimental smallpox vaccine on his own 1-year-old son at the end of the eighteenth century. At the end of the nineteenth century, a 9-year-old child was the first human recipient of Louis Pasteur's rabies vaccine.[7] However it was not until the first half of the twentieth century that regulations governing such experimental therapy began to be established and the importance of consent and parental permission became clearer.

The informed consent of human research subjects was first officially advocated in the Nuremberg Code, a code of ethics that grew out of the trial of German physicians who conducted egregious human experiments in Nazi concentration camps during World War II. However because this important code emphasized the absolute requirement of informed consent, it implicitly excluded children—who cannot give informed consent—from participating in research on human subjects.[8]

The issue was more explicitly addressed in 1964, when the World Medical Association adopted a set of research ethics principles now known as the Declaration of Helsinki.[9,10] This set of principles established the priority of the human subjects' interests over those of science and society, and it sanctioned the participation of children in research if permission was given by the child's responsible guardian.

Interestingly experiments were performed on children after the publication of the Nuremberg Code, which implicitly excluded children from research, and before the Declaration of Helsinki, which explicitly allowed such research under specific conditions. One of the most important of these experiments was a series of radiation exposure experiments. Among participating institutions was the Fernald School in Framingham, Massachusetts and the Massachusetts Institute of Technology with funding from the Quaker Oats Company, in which children deemed mentally retarded were fed radioactive iron and calcium in their cereal.[11] President Clinton's Advisory

Committee on Human Radiation Experiments revealed the ethical consequences of inadequate parental permission in these experiments.[12]

Another important set of experiments on children at that time occurred at the Willowbrook institution (located on New York's Staten Island) and was designed to follow the natural history of hepatitis in children deemed mentally retarded.[13,14] Newly arrived children were infected with hepatitis virus by housing them with others already known to be infected. Participating children were kept in a special unit with better conditions and nutrition, and children whose parents agreed to participation were admitted more rapidly. The lead investigator did require a thorough consent process that included a 2-week waiting period for full deliberation. However because Willowbrook was so crowded, critics subsequently argued that the expedited admission and special treatment amounted to coercion. These two cases underscored the need for ethical review and oversight of human subjects research involving children, even when parental permission is obtained.

The United States Congress became increasingly concerned about research ethics during the early 1970s, in part because of the syphilis study involving poor black men conducted by the U.S. Public Health Service at the Tuskegee Institute. As a result the National Commission for the Protection of Research Subjects of Biomedical and Behavioral Research was formed, and it published the Belmont Report in 1979.[15] This report embraced three principles that are now familiar and accepted as crucial for research involving human subjects: respect for persons, beneficence, and justice. The principle of beneficence acknowledges the Hippocratic maxim "do no harm" and extends it to include maximizing the possible benefits and minimizing the possible harms to research subjects (minimizing harms is often formulated separately as a fourth principle, nonmaleficence).[16] The principle of beneficence is operative in any discussion weighing the risks and benefits of research on human subjects, especially when the subject is a minor. The principle of justice concerns the right and fair distribution of the benefits of research, as well as the burdens, an issue that has a particular urgency when clinical treatment and research are considered globally. The concept of respect for persons includes two principles: that individuals be treated as autonomous agents and that those with less autonomy are entitled to protection. The latter principle is especially relevant in pediatrics and is somewhat fluid in its definition because of the growing autonomy of pediatric patients as they approach adulthood.

Given the past abuse of research subjects who were harmed in studies that they did not understand and for which they had not given meaningful permission, it is understandable that "informed consent" has become the dominant concept in discussion about ethical research on human subjects. However recent arguments have been put forth that informed consent is not always necessary for ethical clinical research, nor is it sufficient to qualify research as ethical. A recent review of major codes and declarations relating to research with human subjects led to the proposal that there be seven requirements for ethical clinical research.[17-20] The research must lead to enhancement of health or knowledge. It must be methodologically rigorous. Selection of study sites and of individual subjects should be determined by scientific objectives and the potential for and distribution of risks and benefits. Given standard clinical practice and the research protocol, risks should be minimized, the potential for benefits should be enhanced, and risks must be outweighed by potential benefits to individuals and knowledge for society. Individuals should be informed about the research and provide voluntary consent. Research subjects should have their privacy protected, have the opportunity to withdraw, and have their well-being monitored. These requirements are thorough and persuasive, but they still must be adapted to the conditions under which the research is conducted. Factors of health, economy, culture, religion, and technology will affect how these requirements are translated into concrete, ethical action. For this reason, the specific context in which the research is conducted will affect ethical deliberation.

Ethical decision making in therapeutic and research efforts for children comprises all of the previously discussed considerations, plus the profoundly salient fact that the recipient of the risk or benefit is not the person who makes the decisions. The minor may not be capable of assimilating sufficient information to meaningfully participate in an "informed choice." One need not enter the arena of international bioethics to find challenges to the role of "autonomy" in ethical decision making: such challenges are the daily fare in pediatric medicine and research, because children's "autonomy" is an issue that changes from day to day.

WHAT IS "CONSENT" IN PEDIATRICS?

The Nuremberg Code provides one starting point for understanding the meaning and importance of informed consent. The statement in this code that "the voluntary consent of human subjects is absolutely essential" has been interpreted as legal capacity, a power of free choice based on knowledge and comprehension.[21] Consent, which was once seen as a single event, has come to be understood to be more of a process.[22] It is not surprising, with the development of guidelines and goals for consent, that the process has become more intentional and more highly scrutinized.

The dominant theoretical framework for morally valid informed consent requires that four criteria be met: disclosure, understanding, voluntariness, and competence. Briefly, the core set of information that must be *disclosed* includes (1) facts (such as risks, benefits and alternatives) that patients (subjects) and providers believe are relevant to the decision, (2) the recommendation of the professional, and (3) the purpose, nature, and limitations of consent. *Understanding* goes beyond disclosure because, although the elements disclosed can be objectively stated, true understanding involves many variables and is more difficult to assess. Establishing and documenting understanding remains a great challenge, because information that has been disclosed but not understood contributes little to the ideal paradigm of informed consent.

Voluntariness—another complex notion susceptible to interpretation—means at least that a decision is made without constraints of coercion or manipulation. Finally, *competence*, which is conventionally understood as the ability to perform a task, has also become a complex concept the definitions of which derive from law, psychiatry, and philosophy. At base a person's competence (or perhaps more accurately expressed as cognitive capacity) to make a particular decision relates to the person's ability to understand and think rationally about available choices, to weigh the benefits and burdens and risks within the context of his or her life and values, and then to use that understanding and logic to make a rational decision.

In the context of complex pediatric medical therapy or research, the process of consent is influenced by the fact that parents are making high-stakes decisions on behalf of their own child. The Children's Cancer Group (CCG) conducted studies that showed that a sense of pressure is perceived by parents when making the consent decision for intervention in the context of childhood cancer.[23] However a more recent study indicated that despite significant dissatisfaction with the consent process among CCG clinician-investigators, most parents were satisfied with it.[24] The same study indicated that the parents' satisfaction did not constitute adequate informed consent.

Even among clinicians assessment of the process of informed consent varies. The experience of the clinician is relevant in this assessment. Simon et al.[25] found that clinicians with 10 or fewer years of experience were more likely to say that the most important goal of informed consent is to explain the disease and treatment and were more likely to suggest to parents that other children might benefit from the research. The same study found that in the end, when reports from clinicians and parents are compared, clinicians are dissatisfied with aspects of consent that parents seem far more satisfied with. For example, clinicians expressed concern about information overload and about the fact that the consent discussion often occurs while the parents are still in a state of shock about the diagnosis.

Further insights into this difference have been gained from a number of studies addressing the perspectives of parents of children with cancer. One such study used three focus groups of parents of children with cancer to retrospectively examine their perceptions of the informed consent process.[26] High levels of stress were consistently reported, which were attributed to efforts to cope with multiple demands, including assimilating their child's diagnosis, nurturing and supporting the child, understanding the information given to them about the diagnosis and treatment, getting to know an entirely new group of people involved in the child's care, and participating in the child's treatment. Another important point was that the parents did not consistently distinguish research from their child's medical treatment. This finding underscores the importance of clearly explaining that research is optional during the process of "informing." If no distinction is made between research and treatment, the goal of informing has not been met. Physician-investigators often experience tension between their role as the patient's physician and their role as a researcher offering participation in a clinical trial designed to contribute to generalizable knowledge. This tension suggests that someone besides the physician-investigator should conduct the consent process. The study also suggested that the nature of clinical research, as well as the difference between research and proven current therapy, might be difficult for parents to grasp.

These conclusions were supported by a second study in which parents of children with newly diagnosed cancer were interviewed.[27] All of the participants recalled the diagnosis, and most (80%) recalled survival statistics. However only slightly more than half knew that the treatment protocol involved research and understood the concept of randomization. This finding is striking when coupled with the fact that three fourths of the parents thought that alternatives to enrollment in a randomized protocol had been insufficiently discussed. Because randomization is such an important tool for answering certain clinical questions, this finding suggests that greater emphasis be placed on explaining unfamiliar concepts during the process of "informing." Again, in this study, the majority of participants were satisfied with the consent process.

A study by Kodish and colleagues[28] confirmed the difficulty of effectively conveying the meaning of randomization during the consent process in pediatric leukemia trials. In this multisite study, informed consent conferences were observed and audiotaped and were then compared with information acquired in interviews with parents shortly after the conference. The investigators found that although randomization was explained in 83% of cases, 50% of the parents did not understand it. Further, parents who did not understand randomization were more likely to consent to the randomized study than did those who did understand it, although this difference was not statistically significant ($P = .07$). These findings led to several recommendations for improving understanding, including a clear explanation of the differences between the randomized trial and off-study therapy, assessment of parental understanding of randomization, and further explanation when the idea was not yet grasped.

Other efforts have been made to improve the process of informed consent in pediatrics, especially in the case of complex clinical trials. For example, a study by the Children's Oncology Group (COG) assessed the possibility of staged consent; investigators had the option of obtaining consent over a 28-day period using a staged approach.[29] This option allowed parents and patients more time to discuss and absorb facts about the disease, the purpose of the trial, the design of the study, and the potential risks. Several measures in this study suggested benefit from the staged approach. There was greater understanding of treatment choices and of the distinction between a randomized controlled trial and standard therapy with the staged approach (80% understanding) than in the other studies (62.5%, $P = .05$).

Contemporary medicine will require the introduction of new methods of informing patients and parents to meet the ethical imperative of informed consent in pediatric trials. Informed consent documents for cancer

Figure 74-1 The Informed Consent Team Link, a prototype device to augment the process of informed consent in phase I trials. This device was developed through multidisciplinary user-centered research and design. The aim of such efforts is to use technological and educational advances to address the widening gap between the average capacity to understand concepts and the advances in medical technology and research.

clinical trials are sometimes long and difficult to understand, with language that serves less to protect human subjects than to decrease institutional liability.[30] Therefore some advances may take the form of technologic and educational methods to explain ever more complex medicine and research to people not formally trained in a medical discipline. One such example is a device known as the Informed Consent Team Link (Fig. 74-1). This device was designed to help families understand phase I trials, which present daunting challenges to fully informed consent. The design was based on information from focus groups of parents, physicians, nonphysician health care workers, and teenaged patients. Among the elements considered important were (1) the need for a "big picture" overview that would create a context for details, (2) delivery of information in small chunks, (3) use of multiple modes of information delivery, and (4) prioritization of information. Such basic observations provided a basis for the design of a device that uses interactive technology, voice, animation, and health education principles to deliver information about phase I trials. Because of children's apparently natural affinity for interactive electronic devices, this approach may be helpful in addressing assent as well.

Concepts about the nature of consent in pediatrics are evolving with changes in contemporary medicine. For example some persons argue that informed consent may be too restrictive a concept and that "valid consent" should be substituted.[31] The three aspects of valid consent are personal competence (Does the patient have the capacity to make the decision?), procedural competence (Is the consent given correctly?), and material competence (Is the procedure consented to appropriate for valid consent?). The concept of valid consent has been explored in the pediatric context by the Society for Industrial and Organizational Psychology Working Committee on

Psychosocial Issues in Pediatric Oncology.[32] The value of this notion, they suggest, is that it emphasizes the patients' or parents' understanding of what is being consented to and recognizes that there are both rational and nonrational aspects to the decision-making process that must be understood. The underlying concern is that informed consent has come to mean legally signed documentation rather than real understanding, insofar as that is possible. Because parents come from different backgrounds and because children of different ages differ in their ability to grasp complex concepts, the level of understanding that is attainable may vary from situation to situation. The notion of valid consent acknowledges this fact and counters the idea that a signed document is equivalent to informed consent.

The four elements of informed consent previously mentioned—disclosure, understanding, voluntariness, and competence—are useful for informed consent in adults, but informed consent in pediatrics is complicated by the fact that three parties are involved (parent, child, and clinician/investigator) and that the research subject is the child. In pediatrics, it is not autonomy (the basis of the four components of consent) that takes precedence but rather the best interest of the child.[33] The best-interests notion is clearer in a purely clinical setting than in a research setting, in which interventions are designed to contribute to general knowledge. Despite the difficulty of approximating truly informed consent in the setting of pediatrics, and especially pediatric research, the obligation to advance pediatric medicine lends urgency to continued efforts to offer the closest possible approximation to informed consent.

One important aspect of the difference between informed consent in adult and pediatric medicine and research is the fact that in pediatrics, informed consent is better thought of as a combination of parental permission and (as appropriate) the more complex concept of the assent of the child.

ASSENT IN CHILDHOOD CANCER TRIALS

The ethics of assent is one of the most difficult issues faced in pediatric clinical trials. Many adolescents, and even some younger children, possess the elements of competence or health care decision-making capacity (setting aside for the moment the legal definitions, which hinge on age rather than capacity). This is especially true, perhaps, of children who are exposed to long-term clinical trials and to the environment of a children's hospital for long periods. Certainly younger children are not developmentally capable of comprehending complex protocols, but they do have some level of understanding that increases with age and experience.[34] How should assent be understood and when should it be required? But first, what do we actually mean by "assent" and how can it be distinguished from consent?

Consent refers to an active affirmative agreement to something by an autonomous agent (i.e., a person). It is capable of being given by anyone who meets the minimal criteria of being in the state of mind and body to be an autonomous agent; generally, most adults would qualify as long as they were not placed in a situation in which their decisions might be suspected to be the result of some form of coercion. The ability to give consent is also context and subject dependent in the sense that most people are generally not competent in all spheres of their lives: for instance, many persons who are perfectly capable to make health care decisions or even agree to participate in research may not be competent to make (informed) decisions about automobile repair. For the purposes of this discussion, the relevant area in which cognitive capacity is important is in the domain of health care (and associated human subjects research). In the United States the legal age of consent is 18 years for most realms (nearly all jurisdictions, however, permit older adolescents who have not yet reached the age of 18 years to make some types of health care decisions [i.e., give consent], usually in regard to reproductive medical issues).[35] Assent is a more complex concept; in general it describes a less active form of agreement to a proposed procedure or action, rather than the more active and involved consent. It is used in an attempt to engage children and adolescents in the process of consent that must be given by parents or other authorized surrogate decision makers.[36,37] However what may qualify as acceptable assent (a grudging or sullen nod of the head or a more energetic and participatory form of positive interaction) remains an area of reasonable concern.

Far less is known about assent than about consent. Much remains to be learned about the practices of institutional review boards (IRBs), the perceptions of parents, clinicians, and children about consent, and the methods that might be most effective in the process of assent. Several studies have looked into these issues and documented the need for further work to address variability in IRB practices and the implementation of assent. One study found that half of IRBs have a method they require investigators to follow when determining which children are capable of assent, whereas half have no such method, and the majority of IRBs rely on investigators' judgment.[38] IRBs need guidance on the implementation of requirements regarding assent. Authors of a second study compared standards for assent, as well as consent forms approved by 55 local IRBs, when reviewing three standardized multicenter research protocols.[39] Standards varied widely; 35 had separate forms and simplified language for assent, and 31 specified lower age ranges for obtaining assent in three studies. For a hypertension study, the age at which assent was required ranged from 6 to 15 years;, for a pain study, the age range was 6 to 12 years; and for a respiratory failure study, the range was 7 to 12 years. It is not clear why some IRBs consider a child of 6 years to be capable of assent while others do not require assent until a child is 15 years old.

Do the regulations help us understand assent? Most research on children is governed by subpart D of 45 Code of Federal Regulations (CFR) 46, which provides additional protections for children (as vulnerable subjects) beyond those specified in subpart A of 45 CFR 46. Subpart D, added in 1983, outlines three categories of research that a local IRB can approve: research not

TABLE 74-2 Categories of Pediatric Research and Requirements for Institutional Review Board Approval

	PROSPECT OF DIRECT BENEFIT	
Level of Risk	**No**	**Yes**
Minimal risk	Approval by IRB permitted (46.404), conditioned on: • Permission from one parent or guardian • Assent of child, unless waived on capacity grounds	
Greater than minimal risk	Approval by IRB permitted (46.406), conditioned on: • Minor increase over minimal risk • Research involves experiences commensurate with those inherent in children's actual or expected medical, dental, psychological, social, or educational circumstances • Intervention or procedure is likely to yield generalizable knowledge about the subject's disorder or condition that is of vital importance for understanding or ameliorating that condition or disorder • Permission from both parents, if reasonably available • Assent of child, unless waived on capacity grounds	Approval by IRB permitted (46.405), conditioned on: • Risks are justified by anticipated benefit to subjects • Relation of anticipated benefit to risk is at least as favorable as that presented by available alternatives • Permission from one parent or guardian • Assent of child, unless waived on capacity grounds or grounds of prospect of direct benefit that "is available only in the context of the research"
Not otherwise approvable, but presents the opportunity to understand, prevent, or alleviate a serious problem affecting the health or welfare of children	Approval requires U.S. Department of Health and Human Services approval after consultation with an expert panel and opportunity for public review and comments (46.407), conditioned on: • Research presents reasonable opportunity to further understanding, prevention, or alleviation of a serious problem affecting health or welfare of children • Permission from both parents, if reasonably available • Assent of child, unless waived on capacity grounds	

From Joffe S, Fernandez CV, Pentz RD, et al: Involving children with cancer in decision-making about research participation. J Pediatr *149:862–868, 2006.*

involving greater than minimal risk to participants (45 CFR 46.404), research involving greater than minimal risk but with the prospect of direct benefit to individual participants (45 CFR 46.405), and research involving no greater than a minor increase over minimal risk (with no prospect of direct benefit) but likely to provide generalizable knowledge of the subject's condition or disorder that is vital to understanding or ameliorating it (45 CFR 46.406; Table 74-2).[40] Local IRBs cannot approve research that does not fall into one of these categories, and performance of the research is possible only if two conditions are met: (1) the local IRB finds that the research provides a reasonable opportunity to further the understanding, prevention, or alleviation of a serious problem affecting the health and welfare of children, and (2) the protocol is approved by the Secretary of Health and Human Services, after soliciting the opinions of an expert panel and providing for a period of public comment (45 CFR 46.407). According to these regulations governing research on children, assent means "a child's voluntary affirmative agreement to participate in research. Mere failure to object should not, absent affirmative agreement, be construed as assent" (45 CFR 46.402). If the IRB determines that the participants in certain categories of age and maturity are capable of providing assent, investigators must obtain it to proceed. When assent is required, a child's refusal is generally binding.

Can an IRB waive the requirement for assent? Yes, but only if (1) the intervention or procedure offers the possibility of direct benefit that is important to the health or well-being of the child and this intervention or procedure is only available in the research context (45 CFR 46.408[a]) or (2) the IRB determines that children below a certain age in a certain situation or with a certain condition have such a limited capacity to participate in the decision that they cannot reasonably be consulted.

The requirements are difficult to apply, especially in the context of clinical trials for childhood cancer. Most of the children are enrolled in research studies in which the therapy is prolonged and carried out in the context of profound physical, spiritual, and psychological stress. The Bioethics Committee of the COG convened an international multidisciplinary task force to address assent in 2003. This group identified a number of problems with the regulatory framework.[41] In brief the regulations do not take adequate account of the dynamic moral and cognitive development of children and thus allow a child either to have no formal role in decision making or to have the power of veto. Nor do the guidelines make clear what constitutes meaningful assent, and so they leave IRBs and investigators with uncertainty about when they have or have not hit the mark (although other groups have provided guidance in this area).[42,43] The regulations do not take into account the fact that some clinical research is more complex than other research, and thus some research may be more accessible to the understanding of children than other research. The regulations say that permission from the guardians and assent from the child are distinct decisions, and they do not take into account the manner in which parents and children make decisions together. Finally, cultures in which autonomy is less emphasized are not accommodated by a regulation

Box 74-1 **Principles Governing Children's Participation in Research Decisions**

1. Investigators should always respect children as persons. In particular, investigators together with parents should honor children's developing autonomy in decisions about research.
2. Investigators should respect parents' roles in guiding their children's moral development and assessing their best interests. For example, parents should have discretion to determine the degree to which children should be encouraged to participate in activities that benefit others.
3. Policies regarding assent, as well as decisions of Institutional Review Boards with respect to particular protocols, should be sufficiently flexible to accommodate the wide range of medical, psychological, and contextual circumstances seen in pediatric oncology.

From Joffe S, Fernandez CV, Pentz RD, et al: Involving children with cancer in decision making about research participation. J Pediatr *149:862–868, 2006.*

that potentially sets parental prerogatives against a child's veto power.[44]

Taking into account these factors, the COG Task Force offered three principles governing children's participation in research decisions (Box 74-1). A number of specific recommendations followed from these principles. The Task Force acknowledged that in some settings the principles offered will sometimes conflict. Therefore the recommendations emphasize the importance of establishing procedures for the resolution of conflict rather than attempting to define universal rules. In that way the absence of universal rules governing decisions in families with, perhaps, different cultural backgrounds and assumptions does not end conversation and negotiation. This approach is especially valuable in an increasingly pluralistic society and a global culture of information sharing. Much work remains to be done to understand the processes of communication and learning and the interactions that comprise the permission-assent process.

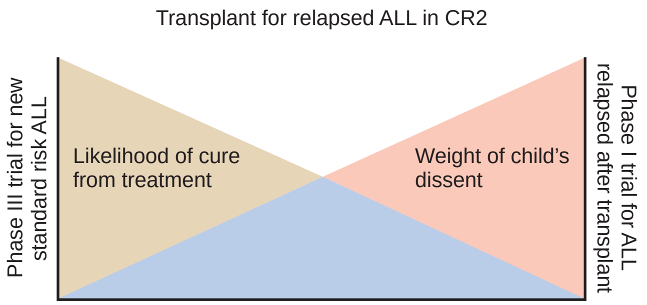
The flexibility of the approach using conflict resolution acknowledges that the obligation to obtain assent may change, depending on the time and situation, even for the same child. For example assent considerations may differ between a 9-year-old child with standard-risk leukemia who may obtain considerable benefit from enrollment in a phase III leukemia trial and a 9-year-old child who has leukemia that has relapsed multiple times and for whom a phase I trial is being considered. Similarly, a child at the beginning of a 2 and one half-year course of therapy for leukemia will be different in age, maturity, vocabulary, experience, and capacity to understand by the end of that course of therapy (Fig. 74-2). Developmentally appropriate approaches to help the child understand the experience do not have the restrictions and limitations that accompany the binding aspects of assent.

For older adolescents assent should be approached in the same way as adult informed consent, even though parental permission may be required.[45,46] Some adolescents may have the capacity for consent but may choose to have their parents make decisions about their participation in research.[47] Several studies have recently assessed assent in adolescents.[48,49] Our understanding of the differences between parents' and adolescents' perceptions of research is growing as we learn more about the assessment of risk (i.e., concern for physical safety) versus aversion (psychological discomfort).[50] More than 3000 adolescents in the United States alone die of chronic illness and cancer each year. In such situations when adolescents meet the criteria for functional competence, the broad ethical consensus is that decisional authority should be granted to them regardless of their legal decisional status.[51] However this is an area in which a wide divergence exists between what ethics may demand but the law allows. Most states and jurisdictions do not permit minors to be sole participants in medical decision making, including consenting to participate in research, unless they have been emancipated according to the laws of the state in which they reside. This restriction does not imply that adolescents should not fully participate in the decision-making process, and there certainly is no legal proscription against their doing so; it simply underlines the difference between good ethical clinical (and research) practice and the legal framework. It might perhaps be better stated that in these situations, if the adolescent is going to be a research subject, assent is necessary but not sufficient.

PEDIATRIC CLINICAL TRIALS

The majority of children with cancer are enrolled in clinical trials.[52] This systematic evaluation of interventions is largely responsible for the dramatic improvement in survival during the past 40 years. A number of important ethical concepts influence the design and execution of these trials. Permission and assent have already been discussed. Other important issues include the distinction between therapeutic and nontherapeutic research, the various concepts of minimal risk and clinical equipoise, and the considerations that distinguish phase I and II trials from phase III trials.

As previously described and in Table 74-2, reports published by the National Commission for Subjects of Biomedical and Behavioral Research formed the basis of current regulations governing research with human subjects, including children. One of the most important



Transplant for relapsed ALL in CR2
Phase III trial for new standard risk ALL
Likelihood of cure from treatment
Weight of child's dissent
Phase I trial for ALL relapsed after transplant

Figure 74-2 The weight of childhood dissent changes as the likelihood for direct benefit (in the form of cure or extension of life) diminishes, as with a patient who goes through a phase III trial for standard risk leukemia, relapses, undergoes transplantation in second remission, relapses, and goes on to consider phase I trials. *ALL,* Acute lymphoblastic leukemia; *CR2,* second complete remission.

distinctions made was between research that does, versus does not, offer the prospect of direct benefit to the child. Some elements of a clinical trial may offer the prospect of direct benefit (for example, chemotherapy for acute lymphoblastic leukemia), whereas other elements may not (e.g., biologic and pharmacokinetic studies designed to improve future trials). What are the general criteria used to determine whether the latter sorts of research are permissible?

Minimal Risk

The central ethical concept that guides discussion of pediatric research that has no prospect of direct benefit is "minimal risk." The Belmont Report defines minimal risk as "the probability and magnitude of physical or psychological harm that is normally encountered in the daily lives, or in the routine medical or psychological examination, of healthy children." The question that immediately arises is which children's lives should be the basis for deciding what is "normally encountered in daily life." These risks can vary widely, not only from country to country but within subgroups in a single country. Even if the notion of "harms or discomforts that average, healthy, normal children may encounter" (as clarified by the National Bioethics Advisory Commission) can be roughly agreed upon as a standard, the question remains whether it is ever acceptable for a parent to give permission for any risk greater than minimal risk in the absence of direct benefit to the child.

Because of concern that the "minimal risk" standard would exclude some pediatric research that is important and appropriate, the National Commission allowed parental discretion in giving permission for research that exposes children to a "minor increase" over minimal risk, given the fact that parents routinely permit their children to participate in activities, such as contact sports, that present more than a minimal risk, and given the potential benefits of such research to others. Therefore a "minor increase" over minimal risk is permissible if the proposed research involves only procedures that such children might normally experience because of their medical condition and if the proposed research has the potential to yield vitally important knowledge for understanding or ameliorating the child's particular condition.

The permissibility of a "minor increase" over minimal risk provides a conceptual way to avoid barriers to important pediatric research. However a difficult question remains: exactly what constitutes a "minor increase"? The term is used in the federal regulations, but it is not defined. Wendler and Emanuel[53] proposed five possible standards for defining a "minor" increase consistently among IRBs. These standards include (1) a fixed percentage above daily risks, (2) the confidence intervals around the risks of daily life, (3) the risks an ill child might encounter in an examination, (4) the "scrupulous parent" standard, in which minor risks are sufficiently similar to the child's past experiences in daily life, and (5) the "socially acceptable" risk standard.

Wendler and Emanuel[53] argue that the fifth standard is the most reasonable. The "socially acceptable" risk standard takes as its starting point the fact that some children encounter greater risks in daily life than others. The socially acceptable risk standard allows risks that are greater than those faced every day by healthy children, but it limits the risks to those that are socially acceptable. The socially acceptable risks greater than those experienced by the average healthy child may be more closely defined through research. In any case this standard tethers the concept of "minor increase over minimal risk" to an evaluation that is nonarbitrary, that does not impede important beneficial research, and that does not justify greater risks for ill children simply because their daily lives are filled with more risk (due to their disease and its treatment).[54] An alternative to the approach taken by Wendler and Emanuel has been suggested by Nelson and Ross.[55] They argue that the "scrupulous parent" standard is ethically justifiable and that such an approach incorporates both minimal risk and a minor increase over minimal risk within a uniform standard that should be applicable to all children.[55]

Phase I and II Trials in Pediatric Oncology

Phase I studies have the unique primary objective of assessing the maximum tolerated dose and estimating toxic effects in human subjects, in contrast to phase II and phase III studies, which explicitly assess the efficacy and relative safety of interventions. Phase I studies in children are important because the pharmacokinetics and toxic effects of drugs differ between children and adults. Therefore if drugs were used in the general pediatric population without phase I testing in children, the incidence of adverse effects would be unpredictable. Additionally some diseases are unique, or nearly unique, to the pediatric population, including a number of pediatric cancers.[56] Prohibition of phase I studies in children would limit the ability of the research community to develop new drugs that target uniquely pediatric diseases.

Phase I studies are typically dose-escalation trials in which some children receive a dose unlikely to be of any benefit while others receive a dose that is toxic. Therefore phase I studies do not fit the category of minimal risk nor, many would argue, of a "minor increase" over minimal risk. Much of the controversy about phase I studies in children, therefore, centers on whether they offer sufficient direct benefit to justify the risks, both from a purely ethical point of view and from the regulatory point of view.

What is the likelihood of harms and benefits in phase I oncology trials? A recent review of abstracts and reports of the results of phase I cancer trials submitted to the American Society of Clinical Oncology (ASCO) from 1991 to 2002 found that the death rate from toxicity was 0.54%, with an overall objective response rate of 3.8%, and that risks decreased over time.[57] A National Cancer Institute–sponsored study of adult phase I oncology trials run between 1991 and 2002 found an overall response rate of 10.6%. The response rates in "classic" single-agent phase I trials were lower (4.4%), whereas those that included at least one Food and Drug Administration (FDA)–approved anticancer agent had a response rate of 17.8%.[58] In pediatric oncology phase I trials, the response rate (both partial and complete responses) has been reported to be between 4% and 9.6%.[59,60] However the (causal) relationship or correlation between dose and response is rarely reported, and the small number of subjects at any dose level would preclude any sort of definitive conclusion from being drawn. The overall rate of death due to toxicity was 0.49%. That said, in any single phase I trial centered around a single drug, considerable variability in outcomes can exist among the research subjects recruited. Hence it is reasonable to conclude that few children entered in phase I trials die from study-drug–related toxicity and a very small percentage may derive some therapeutic benefit. Unfortunately no feasible mechanism exists to abstract what might be called the "pain and suffering" effects of trial participation or whether—as has been reported for adults enrolled in similar studies—there may be an avoidance of engaging in appropriate end-of-life discussions and planning.[61] Finally, at least one study has suggested that parents may feel compelled by their child's physician to enroll in phase I trials.[62] These observations suggest the idea of "collusion" between doctors and patients to temper the discussion of bad news with the hope that may be imparted by treatment.[63]

Can phase I trials be viewed as offering a prospect of direct benefit in the context of pediatric oncology? The pediatric medical and bioethics communities are divided on this question. The fact is that most people who enroll in phase I trials hope for personal benefit, although they know that the trial is designed to test toxicity.[64-66] The concern exists that such a "therapeutic misconception" may encourage false hope for cure and lead parents to make decisions that do not take into account all of the elements that make up "the child's best interest."[67,68] This phrase refers to the mistaken belief by clinical trial subjects (especially those participating in early-phase studies, such as phase I) that the principal purpose or goal of the trial is therapeutic, rather than data generation.[69,70,71,72,73] Clearly the primary scientific goal is not therapeutic, and the fundamental purpose of these trials is to gather data on toxicity, physiologic tolerability, and dosage. However it is very difficult to communicate such bare facts to families. Much of the confusion is derived from the emotional tension of the situation, the hopes and fears of parents (and patients), the fact that treating physicians often are involved in discussing the clinical options available for terminally ill patients, and the mixed messages that are both transmitted and received by families during these conversations.[74-76] The simple fact of the matter is that parents may not wish to hear "the truth" and their physicians may not wish to transmit it. Although many persons consider this problem to be almost insuperable, some attempts have been made to combat it with mixed success.[77] Nevertheless it remains a significant complicating factor that contributes to the ethical complexity of performing pediatric phase I trials.

On the other hand because only patients for whom known therapies have failed are usually eligible for phase I trials, these trials may be viewed as offering a relative prospect of direct benefit, although the chance of controlling the disease is small.[78] Such a view would bring phase I research under CFR 46.405 of the federal regulations, but it has been criticized because such a classification (in which risk is justified by potential benefit) fails to take into account the researcher's focus on safety rather than efficacy. From the latter point of view, phase I research would be approvable only under CFR 46.407, in which the research is reviewed and approved by a panel appointed by the Secretary of the Department of Health and Human Services—a time-consuming effort that requires both national and local IRB review.

One critic of the "direct benefit" argument also questions the approval of phase I trials under CFR 46.407 because the required review process delays providing benefit to children and adds little to the meaningful protection of children. This author has suggested that a new category of research offering the potential for "secondary direct benefit" be added to the regulations.[79] Such a category would require (1) that the risks be justified by the likelihood that the research will yield generalizable knowledge, (2) that the research be commensurate with the lived experience of those with the disease or condition, (3) that the research offer a potential secondary benefit that is otherwise not available (a potential therapeutic benefit even though the trial lacks therapeutic intent), and (4) that consent requirements be met. Work that addresses gaps in the understanding of phase I trials and the federal regulations governing them should take high priority in pediatric medical ethics research. A recent essay supports phase I trials in children using an interesting and somewhat novel argument.[80] Morris[80] suggests that most children who would be eligible for the types of phase I trials that may involve more than minimal risk (independent of how it may be defined) would of course be afflicted with the disease or condition for which the agent under study is under investigation (for future possible therapeutic use). Furthermore it is likely that the experience of this disease would have acquainted both the child and his or her parents with many of the tests and procedures used as part of the trial (such as phlebotomy). Because they would also have an inherent interest in the outcome of such studies (both for the present and the future), they (and local, institutional IRBs) should be extended some moral flexibility in interpreting what should be interpreted as "minimal risk."

Phase II trials play an important role in all areas of cancer therapy. They provide the initial assessment of treatment efficacy and identify agents for further investigation in phase III studies.[81] These studies, although experimental, are clearly therapeutic in intent and thus the therapeutic misconception is not as germane. Phase II studies are likely to increase in number as high-throughput screening of compounds identifies more candidate anticancer drugs and more molecularly targeted agents and biologic agents become available. This fact will raise many important ethical questions in pediatric clinical trials, because phase II studies specifically evaluate drug efficacy before benefit is clearly demonstrated. Therefore it is vital that families and patients be fully informed about alternatives.

We should mention the attraction for incorporating nonrandomized phase II trials into therapeutic phase III studies, the so-called "phase II window." This approach was quite popular for some time because of the belief that previously untreated, "chemotherapy-naive" patients would constitute a population that would better represent the efficacy of a given agent compared with heavily pretreated patients whose response rates might be diminished both because of cross-resistance to other drugs and decreased performance status. This technique has come under significant ethical and statistical criticism, and in 2010, a consensus statement from the National Institute Clinical Trial Design Task Force was issued that called for the elimination of single-arm studies of this type and their replacement with better designed trials (although the Task Force did express the caveat that unique situations may exist in which nonrandomized, window designs might be appropriate).[82,83] Many stand-alone phase II COG studies have had this design, and it is rarely used in phase III studies (only one as of this writing). Therefore although phase II windows and single-arm studies still exist, the future of this form of design is questionable.

Finally, a word should be said about the use of drugs that are still under investigation in an "off-label" capacity. FDA-approved agents have been demonstrated to be safe and effective by FDA standards and thus receive approval for one or more indications. Many of these approved agents that have not yet been shown to have similar efficacy or a justifiable safety profile in children are nonetheless used in a phase II–like practice, but without the protections of an IRB-approved clinical trial (including rigorous and supervised informed consent and an adverse event reporting framework). Data about the frequency of this practice in children have not yet been published, but Peppercorn and colleagues[84] have reported this practice among adult oncologists, even when a clinical study incorporating the same drug(s) and for which the patient is eligible is available. Although it may be imagined that many studies use drugs that are only available via the trial, this situation is not actually the fact in adult oncology. In pediatrics this observation would be even more germane because it is rare for an agent to be available for children (especially for phase II and III trials) without first being tested and approved in adults.[85] The widespread use of this practice is worrisome for several reasons: First, it tends to undermine the clinical trial enterprise if physicians are willing to prescribe (off-label) investigational drugs in the same clinical setting in which they are being investigated. Such use also can lead to the failure to notice uncommon toxicities that may be more easily detected within the stricture of a formal clinical trial. Second, it is argued that such use results in the conduct of research without the significant human subjects oversight. Third, this practice exposes children to more than minimal risk, but the (relative) safety of patients cannot be ensured as it would be in a clinical trial with formal tracking of adverse events.[86] Finally, this practice represents a missed opportunity for more phase II trials to be conducted with sufficient statistical power to enable substantive conclusions about their significance to be drawn.[87,88] Thus this practice exposes patients (subjects) to potential risk without even the compensatory benefit of contributing valuable scientific knowledge to the general community.

Phase III Trials and Clinical Equipoise

If the concept of minimal risk demarcates the upper limit of nontherapeutic research, the notion of clinical equipoise is central (although not unproblematic) to ethical thought about randomization in clinical research. Clinical equipoise requires that if patients are to be randomly assigned to one of two interventions in a clinical trial, real doubt must exist—in the medical community as a whole, if not in the mind of the investigator—about which of the two interventions is superior. This requirement is said to provide one answer to the possible conflict of interest that clinical investigators can experience in the dual role of researcher and physician.[89]

At least two sources of confusion are presented by all forms of clinical trials, especially in pediatrics. First, sick children are first and foremost patients, which creates a special and unique fiduciary relationship between the patient and his or her doctor. This relationship also establishes a duty on the part of the doctor toward the patient that confers certain responsibilities to act in the patient's best interest.[90,91] This relationship should be distinguished from that of an investigator to a research subject, which is defined within the parameters of federal regulations (previously described).[92] In pediatric hematology-oncology, physicians often occupy both roles simultaneously, which can present significant conflicts (although not necessarily straightforward conflicts of interest). For example if the treating physician is also in some way involved in the design or implementation of the clinical trial under discussion with a patient and his family, she (the doctor) may have a conflict. Enrolling in the trial may not necessarily be to the best advantage or well-being of the patient as defined by him (and his surrogates) and his physician, but participating in the trial as a subject could be beneficial to the investigator (the doctor). In these situations it may be advisable for the treating physician to avoid caring for patients with diagnoses that may make them eligible for the trial for which he or she is responsible. For physicians whose relationship to the study is peripheral, in a manner that could perhaps be described as administrative (as is often the case for many, if not most, treating physicians with COG clinical trials), the conflict is minimal. However in a number of institutions, participation in "therapeutic" (i.e., phase II and III) trials may be remunerative, if not to the doctor, to the local group that employs the physician, by way of financial reimbursements to (partially) cover the cost of performing clinical trials. Although these rewards are hardly profitable, they do raise the specter of a conflict and may need to be addressed. A commitment to transparency may be sufficient in these cases. Second—and we admit that this may be more of a theoretical concern—years of experience have demonstrated the enormous benefit bestowed by the cooperative group clinical trial enterprise in pediatric oncology. Of course this progress would only have been possible with the recruitment (by physicians) and participation (by patients/subjects) in many clinical trials during the past four decades. The ongoing dedication of families, patients, and pediatric oncologists to this endeavor has been crucial to its success. Hence it could be perceived that there is a not-so-subtle pressure to enroll as many (eligible) patients as possible in group clinical studies (both therapeutic and nontherapeutic); indeed, failure to enroll sufficient numbers may result in institutional sanctions, up to and including suspension from the Group and thus an inability to access study protocols and documents (see the COG website for details). However, the recognition that this cooperative endeavor has been both productive and protective of patient (and subject) welfare is well understood and accepted. Nevertheless, the conflicts and the potential for their intensification and complexity remains and actually could increase as more pharmaceutical industry clinical trials are incorporated into the cooperative clinical trial group apparatus.

Does the physician's "therapeutic obligation" require the provision of the best possible care or simply of competent care?[93] The concept of clinical equipoise has been challenged from a number of perspectives. Some critics argue that therapeutic medicine and clinical research are distinct types of activity that require distinct ethical frameworks and that the concept of "clinical equipoise" cannot provide a unifying ethical framework.[94,95] Clinical equipoise has also been criticized as especially problematic in developing countries, where the lack of resources may not support trials that test new treatments against established therapies or placebo. The requirement for clinical equipoise could make it difficult to justify the search for interventions that, although they provide significant benefit for less money, are known not to be the most effective interventions.[96,97]

Several other considerations are important in evaluating the concept of clinical equipoise. First, the conditions for establishing true equipoise are not objective, based as they are on unverified judgments that are open to bias.[98,99] Second, if clinical equipoise is not always a reliable foundation for randomized studies, how do we resolve the conflicts that can be posed by clinical investigators' dual roles? Finally, although adults may be able to negotiate the ambiguities of clinical equipoise in a clinical trial, children cannot do so. In light of the previous discussion regarding the best interest of the child (or the attempt to avoid harm to the child), no phase III randomized pediatric trial should be conducted unless genuine doubt exists about which of two or more alternatives is better.

Recently a new approach to bringing together research and clinical care has begun to emerge. The Institute of Medicine has called for the transformation of health systems into "learning health care systems" that are able to study and continuously improve their practices. Learning health care systems pursue a wide range of investigations, including those aimed at quality improvement and better clinical effectiveness. An active question is whether the data collection and monitoring central to learning health care systems should be construed as research, and if so, what type of ethical oversight it should have.[100]

Finally, a great deal of discussion has ensued about the responsibility of investigators to communicate the results of clinical trials to patients and their families, irrespective of the outcome of the studies. Surveys have suggested that patients who have enrolled in trials (or who have been enrolled by their parents) retain an interest in the outcome.[102-105] Thus there is good reason to believe that a continuation of the respect we pay to patients, and the diligence and responsibility owed to study participants/subjects, would warrant the formal reporting of the results of trials to them, even taking into consideration the time lag that is intrinsic to the completion of a large study, the maturing of the data, and the challenges associated with communicating complex information of this type. Furthermore, the variety of data that can be collected from the trial—including intricate genetic and other biologic marker data—will require careful consideration to decide what information would be most important to communicate. The issue of conveying genetic or genomic information has proven to be particularly problematic, and to date the challenge has resisted consensus solutions.[106-108]

SPECIAL CONSIDERATIONS FOR CANCER TRIALS USING ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Many patients with high-risk cancers (especially leukemias) that are resistant to standard chemotherapy may be cured with hematopoietic stem cell transplantation (HSCT). As in other areas of pediatric oncology, most such patients are treated according to research protocols or treatment plans recently derived from research protocols. Because of the continuing, rapid changes in the field of HSCT, ethical considerations, such as the specifics of the risk/benefit analysis, are rapidly changing as well.

The issues that apply to pediatric oncology trials in general are also relevant to those that include HSCT. However HSCT raises additional questions. Unlike most phase III trials, transplantation for cancer is usually a second-line medical procedure aimed at cure after a patient has been treated with other therapies. Common indications for transplantation in patients with malignant disease include lack of response to conventional chemotherapy and a known high risk of relapse despite conventional therapy. In both cases patients have been treated prior to transplantation, and the education received in this experience will be relevant to the consent process (the same, of course, can be said for phase I trials). Patients' and parents' familiarity with the language of pediatric oncology makes the discussion about transplantation easier in some ways than the discussion about a phase III trial in the context of a newly diagnosed childhood malignancy. However these considerations are primarily cognitive. What about other issues?

No studies have examined noncognitive considerations in consent for pediatric HSCT, but one study addressed the relative value of receiving full information in decision making among adult patients.[109] The findings provide interesting information that might in part guide future assessments of the unique characteristics of consent and assent in pediatric HSCT. The study had an unusual hypothesis: in the context of a potentially life-saving procedure, when there are no treatment alternatives that have a reasonable chance of cure, factors other than the effort to fully inform have the greatest influence on the patient's decision-making process. The notion of "voluntary" action is complex in such cases, because the patients' life-threatening illness has "forced" them to consider HSCT as an option. Four factors were considered by patients, according to this study: (1) a full understanding of the treatment, (2) trust in the physician, (3) trust in the treatment team, and (4) the best chance for a good outcome. The most important factor was "best chance for a good outcome," and the least important factor was "a full understanding of the treatment."

This finding is relevant to any high-risk, complex intervention (such as transplantation) in which the patient's life is at stake. The lack of alternative therapies that offer the real possibility of cure limits the voluntariness of the decision, and trust in the physician and the health care team may become more significant than understanding of the treatment. Given the vulnerability of these patients, this fact underscores the importance of careful attention to the therapeutic rationale of treatment, as well as the relationship of the patient and family to the health care team, especially when the intervention has not been established as the standard of care.

Another significant difference between cancer chemotherapy trials and those using allogeneic HSCT is the fact that HSCT involves two patients—the recipient and the donor. Different issues arise depending on whether the donor is a matched unrelated, matched related, cord blood, or haploidentical donor. These differences are, in part, based on the fact that the matched unrelated donor is a stranger, the matched related donor is a brother or sister, and the haploidentical donor is usually a parent. The patient's course and outcome affect the donor in various ways, depending on the relationship of the donor to the patient, and this effect is relevant to the ethical issues involved in HSCT cancer clinical trials.

More than 7 million people are registered as potential bone marrow or peripheral blood stem cell donors for the 70% of candidates for HSCT who do not have a matched sibling donor.[110] The risks of bone marrow donation are small; life-threatening complications occur in approximately 0.1% of healthy donors.[111] Ninety-five percent of peripheral blood stem cell (PBSC) donors do well with only minor complaints.[112] In matched unrelated–donor transplantation, one must consider the donor's rights as well as the patient's rights. These issues were outlined in a review by the World Marrow Donor Association.[113] First, donor autonomy must always be honored. At a minimum, this means that the consequences of each act in the process (as they bear on both the donor and the patient) must be explained to the donor. The informed consent process and document must stipulate the donor's right to withdraw at any time (even during the pretransplant conditioning) and must state the possible consequences of withdrawal. The donor registry cannot pressure or coerce donors, although the center/registry has the right to exclude a donor.

No one is obligated to join a donor registry, but a donor who does join a registry with clear knowledge of the expectations voluntarily incurs some moral obligation. This obligation grows as the process continues: a donor at the point of donation for a patient who is being conditioned has a greater obligation than does a person who is only at the stage of registering, because the patient has undergone a treatment that creates considerable vulnerability and has done so because of the expectation that the donor will follow through. Therefore donor centers are obligated to communicate clearly with donors to avoid disrupting the recipient's treatment plan if possible.

Limits exist to a donor's obligation. Sometimes a clinical situation is such that optimal care of a patient would require additional cell products from the donor, such as T cells or additional stem cells. The donor does not have a legal obligation to continue donating cells or bone marrow after the original donation.

Donor unavailability remains a problem that bears upon decision making because the treatment plan is dependent upon such variables. When donor unavailability rates over 1 year were examined by the National Marrow Donor Program, the worldwide registry of volunteer unrelated stem cell donors, some interesting facts were discovered.[114] Initially when a donor search is started, a request is made for confirmatory typing. Approximately 20% of all donors were permanently deferred at the time of confirmatory testing, and another 12% were temporarily unavailable (because of such things as pregnancy, high-risk exposure, job change, and location change). Donation centers differed considerably. The self-identified racial or ethnic group of the donor affected the likelihood that the donor would be available when requested. These findings suggest important areas in which practical improvement might be achieved: better medical screening, better collection of contact information, better education about the details of the commitment, and movement toward a pressure-free environment. Other important issues that bear upon ethical decision making, such as cultural sensitivity and route of contact, must be studied further. The overall goal is to structure the donor registry in such a way that donor availability is maximized through better recruitment, retention, and contact.

A second important source of hematopoietic stem cells in pediatric oncology transplant trials are sibling donors, many of whom are minors. Although the process of donation has been designed to minimize the coercion of unrelated donors, sibling donors may experience a variety of pressures. The ethical question centers on the coercion of a younger child who is dependent on the parents to provide permission for the donation. One central related ethical question concerns what, if anything, constitutes a benefit to the donor. The sibling donor can experience psychological, spiritual, and physical stress like that experienced by the HSCT recipient. The pain and anxiety among adult sibling donors of bone marrow or PBSC has been described.[115-118] Further, refusal to donate can be perceived as resulting in the loss of a sibling, even though the loss is actually due to the underlying disease. Because the variable of developmental age is added in pediatrics, the issue is more complex. Whether or not the transplant actually occurs, if the sibling dies, the complexity is compounded.[119] In many areas of family life, parents are allowed to give more weight to the interest of one child than to those of another or of the family in general; therefore some persons advocate leaving the decision of whether a minor child should donate bone marrow to a sibling in the hands of the parents.[120] Regardless of how such issues are ultimately resolved, the sibling donors clearly deserve all developmentally appropriate information at the beginning of the process and full psychological support throughout and after the procedure.

Sibling donor interviews provide helpful information. Irrespective of transplant outcome, pediatric sibling donors report a perception of having "no choice" about becoming a donor, whether the sense of constraint is derived from outside pressure (indicated by participants' use of the words "guilt," "propaganda," "privileged," and "conned") or from the donor's own beliefs.[121] Hesitancy may arise not from a lack of concern for the sibling's health but rather from fear of the procedure and of pain. Donors whose recipient sibling died offered a unique perspective. Anger, guilt, and blame were common emotions expressed and seemed to be most difficult to deal with in cases in which the death was directly related to graft failure or graft-versus-host disease. These issues have not been studied enough to draw substantial conclusions, but enough is known to raise questions about competence to consent, the weight accorded to a child's refusal to donate, the limits of the parents' decision-making power, and the worrisome specter of what may constitute battery in the face of a child's refusal. One might override the refusal of a 5-year-old, but what about that of a 10-year-old, a 13-year-old, or a 17-year-old?

Another important issue in the case of sibling donors for pediatric HSCT is the fact that siblings who are not chosen as donors are susceptible to ambivalent feelings of relief, disappointment, and guilt.[122] If siblings are involved in the screening process, issues of psychological well-being and respect for persons meet. In one study that compared sibling donors with sibling nondonors, nondonors had more school-related problems than did donors, and a third of siblings in both groups reported moderate to severe posttraumatic stress.[123-125] Medical encounters with a nondonor sibling may well show suffering that would not have occurred apart from the process of being screened for stem cell donation. Caregivers owe this person as much respect as they owe any patient.

Both case and common law have reasonably established that potential donors who have achieved legal majority (age 18 years or emancipation by a court) may not necessarily or generally be compelled to donate bone marrow (or other organs) irrespective of who the prospective beneficiary may be and the relationship between the two (although the legal history of this situation is complex).[126] The state of affairs for minors who are possible donors is considerably more involved. In 2010 the Committee on Bioethics of the American Academy of Pediatrics (AAP) endorsed the view that minors could serve as donors provided that five conditions were met: (1) "there [should] be no medically equivalent histocompatible adult relative who is willing and able to donate; (2) there [must] be a strong personal and positive relationship between the donor and recipient … this is important, in part, to increase the likelihood that the donor will experience some psychological benefit; (3) there [should] be some likelihood that the recipient will benefit from transplantation; (4) the clinical, emotional, and psychosocial risks to the donor be minimized and be reasonable in relation to the benefits expected to accrue to the donor and the recipient; and (5) parental permission and donor assent be obtained."[127] The AAP also suggested that a "donor advocate" be appointed to help the donor "… (and parents) understand the process and procedures and to protect and promote the interests and well-being of the donor. As such the donor advocate … should not be involved in direct patient care of the potential transplant recipient." The statement did not describe any further the identity of this advocate. Although presumably he/she could be a guardian ad litem appointed by a court, we suspect most institutions would wish to avoid the potential cumbersome process of applying to a court unless necessary. Not surprisingly this position has generated some controversy, including the opposition of the parent (whose child had severe aplastic anemia and who received a sibling marrow transplant) and other objections to the donor advocate requirement.[128,129] The AAP (and others) defended this requirement, and at present their position stands.[130,131]

However a recent case from Alabama in which a 6-year-old girl was required to "donate" split-thickness skin for grafting onto her severely burned identical twin sister suggests that the legal landscape for these cases may still be in a state of some flux.[132] Does this case (and others like it) suggest that under certain conditions involving desperately ill children who may possibly benefit from an allogeneic stem cell transplant, a minor sibling can be compelled to be a donor? Although the image of a child being forced to undergo a painful procedure, protesting all the way, is disconcerting, one can certainly imagine forms of parental pressure that are brought to bear to persuade a reluctant child to proceed with donation. Indeed the opposition to the possibly interdictive role of the "advocate" is the source of at least some of the objections to the AAP position. However most of the cases under discussion (or dispute) concern potential donors who are quite young. For those who may be in the mid to late teenage years, the answer is quite a bit more complicated. As children mature, they become more able to participate in health care decision making, as previously noted. However this increasing cognitive capacity does not accord with the laws in most states that do not extend legal decision-making authority to so-called "mature minors." Nevertheless the legal facts may conflict not only with our moral intuitions but with more mundane biology: it may be physically very difficult (if not completely improper) to force a 15- or 16-year-old to submit to bone marrow or PBSC harvesting if he or she does not agree to be a donor. Indeed the role of the advocate under these circumstances would be superfluous. Unfortunately this fact implies that the objections of a (small) 6-year-old count for far less than those of an adult-sized teenager, even though legally they are similarly inconsequential in the overwhelming majority of states.

A third, increasingly prominent source of stem cells is cord blood. Initial concerns about early clamping of the umbilical cord to obtain the maximum number of cells have been allayed, but other ethical questions remain.[133] Should the cord blood be linked to the identity of the donor so that unsafe units can be identified if the donor is later disqualified (e.g., by genetic testing)? The controversy centers on concerns about loss of privacy for donors. Because the cord blood deoxyribonucleic acid holds genetic information (the social implications of which are not clear at this time), the donor is potentially vulnerable to inappropriate disclosure.[134] A related issue concerns what the limits for cord blood testing ought to be and what one should do with the results. Clearly, some testing is needed to avoid unnecessary risk to the recipient. However in 1994, the Institute of Medicine recommended that children should not be tested for abnormal genes unless the disease has an effective curative or preventative treatment that must be initiated early in life.[135] This view was also endorsed more recently in a comprehensive report from the President's Commission on Bioethics.[136] Thus it may be that samples should be tested broadly to protect the recipient but that the testing should be performed in a blinded way to protect the donor. The details of this issue will require further thought and debate as more is learned about the human genome and prediction of disease. However this approach does not address the use of these samples for general genetic research, which is a related but altogether different question (discussed later).

The fourth source of stem cells used in pediatric clinical oncology trials is the haploidentical donor, usually a parent. The advantage of this sort of transplant is the ready availability of a partially matched donor. No research has been performed on the impact of this sort of transplant on parents and families, but it would not be surprising if the issues seen with sibling donation were compounded when the parent is the donor, including feelings of guilt when the child has severe graft-versus-host disease or graft failure. Another important question is whether there is a limit to acceptable parental sacrifice, and if so, what it is. For example one would not allow a parent to donate his or her heart, but intermediate scenarios include those in which a parent donates a portion of a lung, kidney, or liver in the face of posttransplant complications.

Finally, autologous stem cell reconstitution after myeloablation, mostly for solid tumors (frequently inaccurately referred to as "transplants"), is worth mentioning. Although these procedures do not raise the types of ethical challenges associated with allogeneic transplants of various sorts, they do often take the form of phase II single-arm trials for which little evidentiary support may exist and that are statistically underpowered, as explained earlier in this chapter. The classic example of this situation was the story of stem cell treatment for advanced breast cancer, but similar cases have occurred with childhood tumors as well, including Ewing sarcoma and rhabdomyosarcoma in which apparently excellent outcomes are compared with historic control subjects.[137-140] This observation does not imply that there are not clinical situations in which this therapy may provide significant benefits (as in stage IV, poor-risk neuroblastoma or relapsed Hodgkin disease).[141-143] Although this issue would appear to be straightforward and its resolution similarly so, it has proven to be surprisingly resilient over the years. The significant point is that this intervention can, and should, be used in a manner that is designed to address an important clinical question in a manner that could provide a reliable (and presumably reproducible) answer.

MODELS AND TOOLS FOR ETHICAL DECISION MAKING IN PEDIATRIC CLINICAL TRIALS

As important as the individual issues (such as consent, assent, and clinical equipoise) are, they make the most sense in both the clinical and research settings when they are considered within a larger framework for ethical decision making. Such a framework takes into account fundamental moral principles such as respect for persons, individual and cultural variation, the importance of full information, and the relevance of an individual's experience of illness to the concrete process of decision making. Although it is essential to have a sound foundational understanding of ethical principles as they apply to both the clinical and research settings, it is equally important to emphasize the vital role that facts play. "Good ethics begins with good facts" is an epigram often cited but not trivialized by its pithiness. Comprehensive knowledge about the facts of a case and possession of much information as possible about the patient and his or her family situation can be critical to the pediatric oncologist's role as caregiver and advisor. Incorporated in this approach is also an understanding of the prognosis, along with an appreciation (which should be communicated to the patient and family) of the limits and inherent uncertainty of the prognosis and what this signifies.

The Individualized Care Planning and Coordination (ICPC) model for ethical decision making developed by Baker and colleagues[144] combines the various elements of decision making in such a way that they are intentionally and systematically addressed (to ensure nothing is missed) and revisited using the care model (so that changes over time are acknowledged and responded to). The model begins by establishing a foundation based on the principles of competence, empathy, compassion, communication, and quality (Fig. 74-3). The aims of this model are to attend to quality of life, healing, and suffering from the start of a life-threatening illness. The ICPC model has three steps, each of which has three components (Fig. 74-4, Table 74-3).

The first step, relationship, is made up of three interrelated components: understanding the illness experience, sharing relevant information, and needs assessment. Without comprehending the illness experience of the child and the family, the clinician will be unable to proceed to seeking the best interest of the child and the decision-making process. This may be especially true at the extreme of consideration of phase I clinical trials toward the end of the child's life. Similarly, no decision

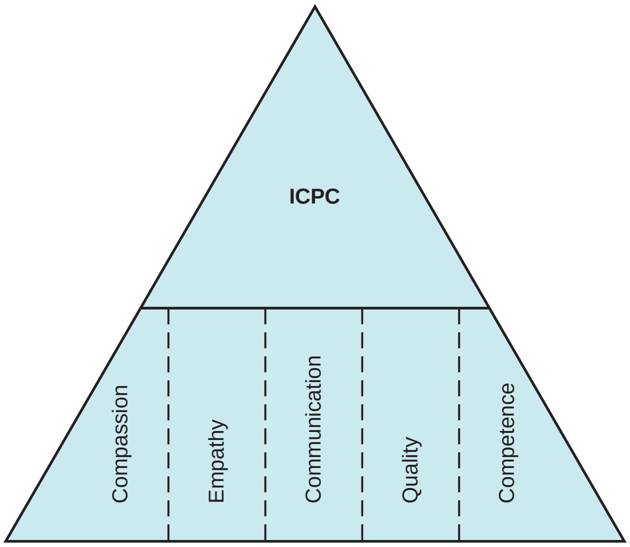


Figure 74-3 Foundation of the Individualized Care Planning and Coordination *(ICPC)* model. *(Modified from Baker JN, Barfield RC, Hinds PS, et al: A model to facilitate decision making in pediatric stem cell transplantation: the individualized care planning and coordination model.* Biol Blood Marrow Transplant *13:245–254, 2007.)*

can realistically address the best interest of the child unless all persons involved in the decision-making process have the needed information. This issue can be difficult when the relevant information is bad news; several studies have shown that the bearer of bad news can elicit strong negative reactions from family members that, in turn, make the clinician reluctant to deliver bad news (an effect known as the "MUM effect").[145-147] Communication of sufficient information for ethical decision making can also be truncated in approximately 10% of cases by lack of training and communication of the pediatric oncologist.[148] A comprehensive needs assessment—not just an assessment of medical needs—is also vital to the process of ethical decision making in both clinical medicine and clinical oncology trials (see Table 74-3). Such comprehensive assessments can inform the decision-making processes by incorporating relevant changes in a patient's needs.

The second step in the ICPC model is negotiation in which goals, prognoses, and treatment options are considered. Although the prognosis for cure can be dynamic because of advances in the science of pediatric oncology, prognostic information is helpful to patients and families as they make decisions.[149,150] Another relevant consideration is that more than one relevant prognosis exists—more, that is, than the prognosis for cure—such as the prognosis for life prolongation and the prognosis for relief of suffering. These two prognoses are relevant, relate intimately to the goals of care, and are profoundly important aspects of ethical decision making in pediatric oncology.

After the range of prognostic elements has been considered, it is possible to move on to a discussion of what the goals are to be—goals that may change as the prognosis changes (Fig. 74-5).[151] In a phase III clinical trial, cure may be the dominant goal. However for a child who has had multiple relapses and whose family is considering a phase I trial, ethical decision making will involve a reassessment of goals in light of the best interest of the child, including a reassessment of the child's expressed values. Assessment and prioritization of the values of the child—especially, perhaps, in the context of a low probability of cure—is an area in which much research remains to be done. Among novel projects being assessed is the use of interactive technologies (tapping into the "video-game" culture) to augment the expressive ability of younger children (Fig. 74-6).

Each potential goal with its associated prognosis is related in turn to a treatment option aimed at achieving the goal to the extent possible (i.e., as limited by scientific progress). If families see that supportive care is available to help them achieve their goals, they are less likely to feel abandoned and to fear discontinuation of therapies with curative intent.[152] Ethical decision making takes into account prognoses, goals, and treatment options and

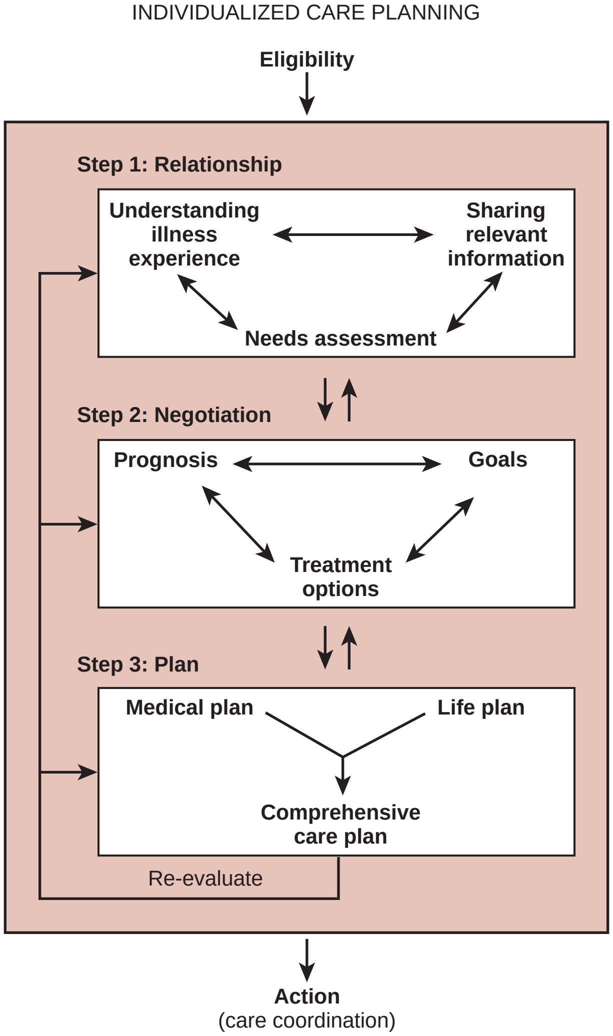

Figure 74-4 The three-step individualized care planning and coordination model. *(Modified from Baker JN, Barfield RC, Hinds PS, et al: A model to facilitate decision making in pediatric stem cell transplantation: the individualized care planning and coordination model.* Biol Blood Marrow Transplant *13:245–254, 2007.)*

TABLE 74-3 Domains of Interdisciplinary Needs Assessment

Assessment Domain	Examples
Structure and process of care	Specialty-level trained symptom management experts are available. The setting of care should meet the preferences, needs, and circumstances of the patient and family. The care plan is based on a comprehensive interdisciplinary assessment.
Physical aspects of care	Symptoms and adverse effects are assessed and managed in a timely, safe, and effective manner. Symptoms and side effects are assessed and managed in a manner that is patient and family centered.
Psychological and psychiatric aspects of care	Psychological and psychiatric needs are assessed and managed in a timely, safe, and effective manner. Grief and bereavement program is available to assess and manage patient, family, and staff grief.
Social aspects of care	Comprehensive interdisciplinary assessment identifies the social needs of patients and families.
Spiritual, religious, and existential aspects of care	Spiritual and existential dimensions are assessed and responded to based on the best available evidence. Spiritual and existential dimensions are approached in a manner that is acceptable to the patient and family as they pertain to the patient's illness.
Cultural aspects of care	Needs are assessed in a culturally sensitive manner. Specific patient and family cultural needs are assessed.
Care of the imminently dying	During this stage of the illness trajectory, the comprehensive needs assessment continues. Signs and symptoms of impending death are assessed, recognized, communicated, and treated as needed.
Ethical and legal aspects of care	Health care professionals assess and attempt to incorporate the values, goals, and preferences of each patient and family. The need for ethics consultation should be assessed based on the comprehensive needs assessment and discordant steps in the process (i.e., cure as a primary goal in end-stage cancer).
Informational aspects of care	Comprehensive interdisciplinary assessment identifies the informational and educational needs of patients and families. Specific patient and family information is provided in a timely manner.
Relational aspects of care	As a part of the generation of a life plan, the relational needs of the patient and family are assessed. Relationships are assessed and augmented throughout the illness trajectory.

involves shared decision making by the family, the patient, and the clinicians. This process leads to the third step of the ICPC, the comprehensive care plan.

The ethical decision-making process that yields a comprehensive plan takes into account consent, assent, full disclosure of information, and attention to the variety of ways that families and individuals prioritize values. The comprehensive care plan includes both a medical plan (decisions about medical treatment and symptom management) and a life plan (addressing personal goals and family needs). The former might carry more weight when the goals emphasize cure, and the latter might carry more weight for a patient with incurable disease.[153]

The value of such an approach is that it can clarify complex ethical decision making in settings such as the intensive care unit (with the extraordinary advances in sustaining biologic life) and can clarify the goals of care. A useful tool that complements the ICPC is the "four box" method developed by Jonsen and colleagues,[154] which offers specific questions that can add content to the information categories relevant to comprehensive ethical decision making (Fig. 74-7). This more detailed set of questions in the categories of medical information, family preferences, contextual details, and quality of life expands those put forward by the President's Commission in 1983 and by the publication *Deciding to Forgo Life-Extending Treatment*.[155] The five considerations offered by the Commission for determining the best interest of the child in such situations are the amount of suffering and potential for relief, the severity of dysfunction or the potential for restoration of function, expected duration of life, potential for personal satisfaction and enjoyment of life, and the potential to develop a capacity for self-determination.

These issues are very complex, and it is beyond the scope of this chapter to discuss them in depth. However both the moral and spiritual outlook of families (and the emerging and solidifying views of patients) and physicians can become entangled in an elaborate mixture of feelings and facts that may have a profound influence on the types of decisions that emerge during discussions at or near the end of life.[156,157,158,159,160,161] The often-heard directive to "do everything" may be interpreted in a variety of ways, including offering further therapies both in and out of the context of sanctioned clinical trials. Complicating these clinically challenging situations is the influence of both radical uncertainty about prognosis and the underrecognized influence of anecdotal experience.[162-164] When to transition to comfort care only in the dying pediatric cancer patient—or, for that matter, when to concede that a patient is actually dying—remains a dilemma, but one that should be managed in an individualized manner for each patient and his or her family.

FURTHER CHALLENGES IN PEDIATRIC CLINICAL ONCOLOGY TRIALS

Bioinformatics and Genomics

In the past two decades we have seen an unprecedented increase in the international sharing of information and

History of Present Illness

Summary of history of present illness.

Medical Indications	**Patient and Family Preferences**
Comment on the principles of beneficence and nonmaleficence: • What is the patient's medical problem? History? Diagnosis? Prognosis? • Is the problem acute? Chronic? Critical? Emergent or reversible? • What are the goals of treatment? • What are the probabilities of success? • What are the plans in case of therapeutic failure? • In sum, how can this patient and family be benefited by medical and nursing care, and how can harm be avoided?	Comment on the principle of respect for autonomy: • Is the child-patient capable of participating in the decision--making process? Is there evidence of incapacity (e.g., age, cognitive or developmental status)? • If able to participate, what is the extent of that participation? Is the child--patient making decisions about care? If so, what is the patient stating about preferences for treatment? • If able to participate, has the child--patient been informed of benefits and risks, understood this information, and given consent? • If incapacitated or unable to participate, who is making decisions on his or her behalf? Is the parent or surrogate using appropriate standards for decision-making? • Has the patient, parent, or surrogate expressed prior preferences (e.g., Advance Directives)? • Is the patient, parent, or surrogate unwilling or unable to cooperate with medical treatment? If so, why? • In sum, are the patient and family's rights to choose being respected to the extent possible in ethics and law? Do they know they have a choice?

Quality of Life	**Contextual Features**
Comment on the principles of beneficence, nonmaleficence, and respect for autonomy: • What are the prospects, with or without treatment, for a return to normal life? • What physical, mental, and social deficits is the patient likely to experience if treatment succeeds? What is the impact on the family? • Are there biases that might prejudice the provider's evaluation of the patient's quality of life? • Is the patient's present or future condition such that his or her continued life might be judged undesirable? • Is there any plan and rationale to forego treatment? • Are there plans for comfort and palliative care?	Comment on the principles of loyalty and fairness: • What are the rights of the child relative to the rights of the family? • Are there family issues that might influence treatment decisions? • Are there provider issues that might influence treatment decisions? • Are there financial and economic factors? • Are there religious or cultural factors? • Are there limits on confidentiality? • Are there problems of allocation of resources? • How does the law affect treatment decisions? • Is clinical research or teaching involved? • Is there any conflict of interest on the part of the providers of the institution?

Discussion

Summary of key discussion points.

Plan

Summary of action plan.

ideas. This fact has allowed more rapid dissemination of useful information and has also increasingly uncovered disparities in access to technology, availability of resources, and ethical values, all of which bear on the ethics of pediatric clinical oncology trials when considered from a global perspective.

Technological advances that are revolutionizing the diagnosis and treatment of childhood cancer (and other childhood disorders) bring with them new ethical issues.[165] These complex ethical questions challenge us to develop a coherent approach that accommodates the diversity of political, religious, cultural, philosophical, and vocational backgrounds that bear upon the discussion.

Bioinformatics is one area demonstrating rapid advances. Bioinformatics attempts large-scale organization of information, including genomic data, protein expression data, and molecular interactions.[166] Genomics is revolutionizing the diagnosis and treatment of cancer.[167] High-throughput microarrays can profile the expression patterns of tens of thousands of genes simultaneously.[168] This technology offers much promise. Similarly, it raises a number of important ethical questions. If a disease gene or disease susceptibility gene profile is discovered, should a subject be notified? Should the subject's family also be notified, or is this a breech of confidentiality?[169]

ASCO has recommended that genetic testing for cancer predisposition be offered when (1) the individual has a personal history, family history, or features suggestive of genetic cancer susceptibility, (2) the test can be adequately interpreted, and (3) the result will aid in a diagnosis or in the medical or surgical management of a patient or family member who has a hereditary risk for cancer.[170] ASCO has also recommended that the regulatory oversight of laboratories providing such tests be strengthened and that federal laws be established to prohibit discrimination by health care providers, employers, and insurance agencies on the basis of such information. Although some persons maintain that genetic discrimination will not affect insurance coverage, several surveys have shown that the public fears this possibility.[171,172,173] One important legislative step that has been taken to address these concerns is the Genetic Nondiscrimination Act of 2008 (Box 74-2).[174]

Box 74-2 Genetic Information as Defined by the Genetic Information Nondiscrimination Act of 2008

- An individual's genetic tests (including genetic tests done as part of a research study).
- Genetic tests of the individual's family members (defined as dependents and up to and including fourth-degree relatives).
- Genetic tests of any fetus of an individual or family member who is a pregnant woman, and genetic tests of any embryo legally held by an individual or family member utilizing assisted reproductive technology.
- The manifestation of a disease or disorder in family members (family history).
- Any request for, or receipt of, genetic services or participation in clinical research that includes genetic services (genetic testing, counseling, or education) by an individual or family member.
- Genetic information does not include information about the sex or age of any individual.

From Office for Human Research Protections, Department of Health and Human Resources: Genetic Information Nondiscrimination Act of 2008. Accessed June 10, 2014 at www.hhs.gov/ohrp/policy/gina.pdf.

In pediatric oncology, the ethical issue is even more complex because surrogate decision makers make decisions that may affect the research subjects' future employability, insurability, and privacy. Further, as technology grows more complex, the gap between technology and meaningful understanding on the part of the family/patient widens (a growing challenge to "informed consent"). Can the surrogate decision makers understand fully the implications of their decision? How much can be expected of a parent without special training?

Pharmacogenomics is the subcategory of genomics research that has perhaps the most immediate potential impact in pediatric clinical oncology trials. This area, too, has enormous potential to benefit children but also creates the potential for social and economic discrimination and abuse of information in genomic databases. Pharmacogenomics combines human genomics with pharmacogenetics to study the role of the individual's genetic makeup in the individual's response to a drug.[175] The promise of this approach is that patients can receive individually tailored medical therapy and dosing. This technology advances the important concept of risk stratification, which historically has led to better protection of children with lower risk cancers from excess toxicity while ensuring that children with higher risk disease are not undertreated.

Pharmacogenomics raises several ethical questions. For example an economic question exists: Might pharmacogenomic criteria eventually become regulatory requirements for the development and testing of medicines?[176] Because the pharmaceutical industry functions on a business model, it is unlikely to develop medicines that will benefit only a small, narrowly defined group of patients. This dilemma is familiar to investigators in pediatric oncology. Orphan drugs might therefore become more common. How should economic risk be weighed against the potential clinical benefit for a small group of patients? Second, if pharmacogenomics information suggests only that a child is more or less likely to benefit from a drug, what likelihood threshold would exclude the child from the use of a drug? Ten percent? Thirty percent? If a child is less likely to respond to a drug, is an insurance company obligated to pay for the drug?[177] If genetic variance peculiar to an ethnic group is found, what are the political, social, and economic implications? Might these be used to decide whether to develop certain medicines for certain populations?[178]

Globalization

Such questions about the impact of technology present a contrast to the ethical issues involved in pediatric oncology trials in low-income countries.[179] The cure rates of many diseases in children differ substantially between high-income and low-income countries.[180] The interventions that have the greatest impact in such countries are often not therapies per se but are rather aimed at reducing the substantial relapse rate caused by, for example, abandonment of treatment—the main cause of treatment failure in low-income countries. Remedial interventions

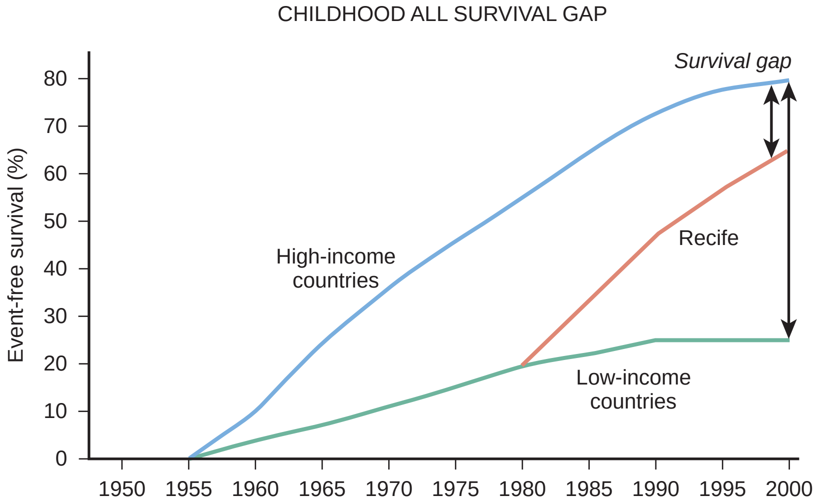

Figure 74-8 Five-year event-free survival of children with acute lymphoblastic leukemia in high-income countries versus low-income countries. Interventions to reduce the loss of patients to follow-up (e.g., making work available near the hospital so the parents are able to make sufficient income to feed other children) increased the survival rate in Recife, Brazil. *(Modified from Howard SC: Delivering global oncology care. Accessed June 10, 2014 at* http://www.cure4kids.org/public/873.*)*

can have a significant impact.[181] St. Jude Children's Research Hospital collaborated with a pediatric cancer center in Recife, Brazil, to reduce abandonment of therapy by providing family support such as housing, work, and food, and the 5-year event-free survival rate of children with acute lymphoblastic leukemia rose from 32% in the 1980s to 63% in 2000 (Fig. 74-8). Similarly, in El Salvador, the 4-year survival rate for children with acute lymphoblastic leukemia increased from 5% to 46% for high-risk cases and 69% for standard-risk cases.[182] Such success has underscored the promise of international collaborative clinical care and research for children with cancer. Many challenges remain, however.

One important challenge is that of ethical oversight of international research in pediatric oncology. Researchers in low-income countries often have little or no access to a functional research ethics committee. However institutions in high-income countries require (in part under the guidance of federal regulations) that adequate ethical oversight be in place as a prerequisite for cooperative clinical research. Collaborative research that uses the strategy of "twinning" institutions in high-income countries with those in low-income countries can produce important advances, as previously described, but the lack of ethical oversight can preclude these collaborations. Researchers cannot report such work in high-profile journals. The International Committee of Medical Journal Editors requires that reports of research involving human subjects document established mechanisms of human subject protection.

The Council for International Organizations of Medical Sciences guidelines state that researchers and institutions in high-income countries sponsoring research in low-income countries have an ethical obligation to improve the capacity for human participant protection in these countries. However in a survey of 203 clinical researchers in low-income countries, 44% reported that their studies were not reviewed by the country's ministry or department of health, and 25% reported that their studies underwent no ethical review by a research ethics committee, IRB, or ministry or department of health.[183]

Federal regulations require that clinical trials conducted in low-income countries in collaboration with U.S. institutions must meet the ethical standards for trials based in the United States. However within the framework of these ethical standards, the research procedures can be adapted to local needs, conditions, and culture.[184] Advancing the development of research ethics in developing countries will open future possibilities for international collaboration that can increase the survival of children with cancer worldwide. Such trials do not necessarily require advanced technology to address the root causes of the disparate survival rates of children in low-income versus high-income countries. Addressing this disparity is itself an ethical imperative.

Although performing clinical trials in impoverished countries in an ethically justifiable manner is laudable, it fails to address the issue of whether the results of such studies will be able to be used to practically benefit future patients. For example within the confines of a trial in a developing country, the sponsor may provide the drugs free of charge to the subjects. However once the trial was complete and, say, the experimental arm was proven to be a significant improvement over the control arm of a phase III study for leukemia, would the expensive agents required to bestow the benefits of the therapy be available for future patients to receive and hence gain the advantages of such treatment? It is unlikely that multiple pharmaceutical companies would continue to make their products available without cost in perpetuity. Another approach that has been suggested is to perform trials with truncated versions of the "first world" model in an attempt to discern if less expensive and perhaps simpler options exist to obtain similar therapeutic outcomes. Of course this would be adjusting treatment to acknowledge the reality of the clinical situations in poor countries and hoping to transmit some (rather than no) benefit, but it also preserves an altered standard of care for people (patients) who already endure the excessive burdens associated with poverty.[185,186] In addition the enactment of the (U.S.) Pediatric Exclusivity Provision, which provides a financial incentive to drug companies to study agents in children that have heretofore only been approved in adults, has generated a large amount of international research, but it is unclear whether the subjects and future children for whom the drugs are appropriate but who live outside the home countries of these pharmaceutical companies will continue to benefit.[187,188] How this situation will ultimately settle out and what the landscape will look like remain to be resolved.[189,190]

CONCLUSION

Pediatric clinical trials present some of the most challenging ethical issues in modern medicine. Children are inherently vulnerable, and yet they are in need of the best, most effective, and least toxic therapies. Much is at stake in childhood cancer. New therapies are developed through research, and yet in pediatric trials, the person who is experiencing the risk is not the same person who is deciding whether the child participates. Many questions will require further thought and discussion and empiric research for the questions amenable to such approaches. Children do not have legal status as decision makers, and yet persons who care for children in pediatric clinical trials know how mature a child's perception can be, even that of a young child. What weight should be given to their opinions? More globally, how should we respond to the disparity of wealth in prioritizing pediatric research goals, even within the boundaries of a developed nation? How should we navigate cultural and political differences that influence the ethical considerations in international clinical trials?

Advancing excellent care of children around the world who have catastrophic diseases such as cancer depends upon clinical trials. Good clinical trials require ethical decision making at every level. Two questions regarding advances in therapy for childhood cancer must always be asked at the same time: "What *can* be done next?" and "What *should* be done next?" The means for answering the first question is scientific. The means for answering the second question is often more philosophical, drawing on many sources of wisdom and insight that are not intrinsically scientific in their approach. History has taught us that scientific advances without ethical considerations can become horrific. Similarly, wisdom without scientific advances cannot further the effort to cure sick children. Medical science committed to ethical research offers the best possibility for continuing to advance the care of children with cancer.

   Parents of children newly diagnosed with cancer were interviewed to learn their perspective on the informed consent process for a clinical trial. Recollection for items such as diagnosis, treatment, and general statistics were high, but understanding of certain aspects of clinical trials was low.

28. Kodish E, Eder M, Noll RB, et al: Communication of randomization in childhood leukemia trials. *JAMA* 291:470–475, 2004.

   This report analyzed physicians' explanations of and parents' understanding of randomizations in randomized clinical trials for childhood leukemia. Physicians explained randomization in most cases, but half of the parents did not understand the concept. The presence of a nurse and discussing specific aspects of the clinical trial were shown to increase the understanding of randomization, and parents who did not understand randomization were likely to be of the racial minority and lower socioeconomic status.

39. Kimberly MB, Hoehn KS, Feudtner C, et al: Variation in standards of research compensation and child assent practices: a comparison of 69 institutional review board-approved informed permission and assent forms for 3 multicenter pediatric clinical trials. *Pediatrics* 117(5):1706–1711, 2006.

   This study was carried out to review child participant assent and compensation by looking at informed permission, assent, and consent forms. These forms were found to offer compensation in three instances: reimbursement for travel and food expenses, for inconveniencing the participant, and for the participant's time. Compensation varied between $0 and $1400. Most of the forms included assent documentation, and a little over half included a separate form written for children and specified at which age to provide assent.

50. Brody JL, Scherer DG, Annett RD, et al: Voluntary assent in biomedical research with adolescents: a comparison of parent and adolescent views. *Ethics Behav* 13:79–95, 2003.

   Parent and adolescent perspectives on an asthma research vignette, including a final decision of whether or not to participate, were compared; 74% of the time parents and their children agreed on research participation, with both claiming to be the responsible party for the decision.

53. Wendler D, Emanuel EJ: What is a "minor" increase over minimal risk? *J Pediatr* 147(5):575–578, 2005.

   The additional protections for children involved in research require the interpretation and application of three different levels of risk: minimal risk, minor increase over minimal risk, and more than a minor increase over minimal risk. Wide variability exists in the categorization of various research procedures according to these levels of risk. Noting that the federal regulations do not define a minor increase over minimal risk, the authors propose that this level of risk be interpreted as socially acceptable risks that are nevertheless greater than the risks ordinarily encountered by healthy children (i.e., minimal risk).

55. Nelson RM, Ross LF: In defense of a single standard of research risk for all children. *J Pediatr* 147:565–566, 2005.

   In response to the article on minor risk by Wendler and Emmanuel[53] (2005), this article argues that the ethical justification for this standard appears tautological, endorsing those risks that are "acceptable" to society and rejecting those that are "unacceptable" to society without explaining why certain risks would or would not be considered socially acceptable. As an alternative, the authors believe that the "scrupulous parent" standard is ethically justifiable and incorporates both minimal risk and a minor *increase over minimal risk within a uniform standard that should be applicable to all children.*

59. Kim A, Fox E, Warren K, et al: Characteristics and outcome of pediatric patients enrolled in phase I oncology trials. *Oncologist* 13:679–689, 2008.

    Analyses presented in this article aimed to define characteristics, toxicity risk, and outcomes of pediatric phase I trial participants. A higher risk for a dose-limiting toxicity was associated with drug dose and prior radiation, and the median survival rate was 5 months from the time of subject enrollment.

62. Maurer SH, Hinds PS, Spunt SL, et al: Decision making by parents of children with incurable cancer who opt for enrollment on a phase I trial compared with choosing a do not resuscitate/terminal care option. *J Clin Oncol* 20:3292–3298, 2010.

    Decision making for parents who just enrolled their child on a phase I trial and those who had chosen a do not resuscitate order or terminal care were compared. They were asked for the rationale of their decision, how they define a good parent, and what clinician behaviors supported this definition. Both groups desired clinician support and believed a good parent was supportive, present, and sacrificed for the child. Participants who chose a clinical trial indicated that they felt compelled to continue with care, whereas the other group expressed quality of life concerns.

66. Tomlinson D, Bartels U, Hendershot E, et al: Factors affecting treatment choices in paediatric palliative care: comparing parents and health professionals. *Eur J Cancer* 47:2182–2187, 2011.

    Factors influencing parents' and health care professionals' decision making for chemotherapy or supportive care in pediatric palliative care were compared. Parents rated hope, increased survival time, and the child's quality of life as most important to their decision, which were significantly higher than the physicians' ratings. Physicians placed a higher importance on the family's financial considerations.

71. Miller FG, Brody H: A critique of clinical equipoise. Therapeutic misconception in the ethics of clinical trials. *Hastings Cent Rep* 33:19–28, 2003.

    A predominant ethical view holds that physician-investigators should conduct their research with therapeutic intent. Because a physician offering a therapy would not prescribe second-rate treatments, the experimental intervention and the best proven therapy should appear equally effective. "Clinical equipoise" is necessary. The authors argue that this perspective is flawed, that the ethics of research and of therapy are fundamentally different, and that clinical equipoise should be abandoned.

76. Cousino MK, Zyzanski SJ, Yamokoski AD, et al: Communicating and understanding the purpose of pediatric phase I cancer trials. *J Clin Oncol* 30:4367–4372, 2012.

    Parents of children enrolled in a phase I clinical trial were interviewed and their responses were analyzed for understanding of three core components of a phase I trial: dose escalation, dose limiting toxicity, and safety. Physician disclosure was also measured. The child was present in 83 of the 85 conferences analyzed. Only a third of parents exhibited understanding of the scientific goals, and another third exhibited no understanding. Parents of a higher socioeconomic status and racial majority status were more likely to understand. Physician explanation of goals were associated with parent understanding but were not explained in all cases.

77. Marshall PA, Magtanong RV, Leek AC, et al: Negotiating decisions during informed consent for pediatric phase I oncology trials. *J Empir Res Hum Res Ethics* 7:51–59, 2012.

    Sixteen informed consent conferences for a pediatric phase I trial were examined to identify communication steps and what influences the negotiation. It was found that families and patients attempt to gain control and autonomous decision making by negotiating microdecisions in drug logic and logistics and administration and/or scheduling, which unfold in a four-step process.

108. Kollek R, Petersen I: Disclosure of individual research results in clinico-genomic trials: challenges, classification and criteria for decision-making. *J Med Ethics* 37:271–275, 2011.

    Although an ethical obligation to report findings of clinical research to trial participants is increasingly recognized, it is unclear how such a process should be organized. The authors present a classification of different actors, processes, and data involved in the feedback of research results pertaining to an individual. They go on to discuss the types of difficulties that must be faced when returning individual research results to trial participants and present a stepwise model to trigger the individual feedback process.

121. MacLeod KD, Whitsett SF, Mash EJ, et al: Pediatric sibling donors of successful and unsuccessful hematopoietic stem cell transplants (HSCT): a qualitative study of their psychosocial experience. *J Pediatr Psychol* 28:223–230, 2003.

    This study was a qualitative review of the psychosocial experience of pediatric sibling donors' successful and unsuccessful hematopoietic stem cell transplants. Siblings who were in the unsuccessful transplant group had a higher negative impact, reported feelings of guilt, and were less likely to experience positive effects. According to both groups, psychological aspects were of greater importance than physical aspects.

126. Coleman DL, Rosoff PM: The authority of "mature minors" to consent to general medical treatment. *Pediatrics* 131:786–793, 2013.

    The law has developed a broad "mature minor exception" to the general requirement of parental consent in abortion cases and has additionally carved out numerous specific status-based and condition-based exceptions to that requirement. Because of this, it is not always easy for medical professionals who treat adolescents to ascertain the applicable law. In this article, the authors discuss the underlying differences between medical ethics and law that have caused some of the confusion in this area, and they set out the most current legal rules governing adolescent decision-making authority in general medical settings.

134. Sugarman J, Kaalund V, Kodish E, et al: Ethical issues in umbilical cord blood banking. Working Group on Ethical Issues in Umbilical Cord Blood Banking. *JAMA* 278:938–943, 1997.

    Umbilical cord blood (UCB) technology is increasingly important. In this article the authors argue for several important conclusions regarding UCB. UCB banking for autologous use is associated with even greater uncertainty than is banking for allogeneic use. Marketing practices for UCB banking in the private sector require close attention. There must be continued work to ensure that recruitment for banking and use of UCB are equitable. The process of obtaining informed consent for collection of UCB should begin before labor and delivery.

144. Baker JN, Barfield RC, Hinds PS, et al: A model to facilitate decision making in pediatric stem cell transplantation: the individualized care planning and coordination model. *Biol Blood Marrow Transplant* 13:245–254, 2007.

    The authors introduce the individualized care planning and coordination (ICPC) model as a practical approach to facilitate ethical and effective decision making in pediatric stem cell transplantation settings. The ICPC is a three-step model comprising (1) relationship—understanding the illness experience from the perspective of the patient and family, sharing relevant information, and assessing ongoing needs; (2) negotiation—prognosticating, establishing goals of care, and discussing treatment options; and (3) plan—generating a comprehensive plan of care that includes life and medical plans. Based on a foundation of a care of competence, empathy, compassion, communication, and quality, the ICPC model aims to diminish contentious family-staff interactions that can lead to mistrust and help guide treatment decision making.

148. Hilden JM, Emanuel EJ, Fairclough DL, et al: Attitudes and practices among pediatric oncologists regarding end-of-life care: results of the 1998 American Society of Clinical Oncology survey. *J Clin Oncol* 19:205–212, 2001.

    Members of the American Society of Clinical Oncology were surveyed to gain an understanding of the attitudes, practices, and challenges its members experience when caring for end-of-life care patients. Clinicians reported a lack of formal education in pediatric palliative care and a need for strong mentors. The absence of a palliative care team was reported as impeding quality care for patients and reducing the effectiveness of communication between clinicians and patients.

153. Whitney SN, Ethier AM, Fruge E, et al: Decision making in pediatric oncology: who should take the lead? The decisional priority in pediatric oncology model. *J Clin Oncol* 24:160–165, 2006.

    The authors propose a new model of decision making in pediatric oncology to reconcile the discrepancies that exist between *how ethicists and clinicians view the decision-making process for patients. Emphasis is placed on distinguishing decisional priority from decisional authority and on having clinicians encourage parents to assume decisional priority for their child.*

156. Curlin FA, Chin MH, Sellergren SA, et al: The association of physicians' religious characteristics with their attitudes and self-reported behaviors regarding religion and spirituality in the clinical encounter. *Med Care* 44:446–453, 2006.

The relationship between physicians' religious beliefs and their self-reported behaviors on religion and spirituality in the clinical setting was examined. Clinicians indicated that it was appropriate to discuss these topics when the patient initiates the discussion and that they often are encouraging of the patients' own beliefs and practices. Clinicians who indicate they are more religious are more likely to address religion and spirituality in the clinical setting.

158. Ecklund EH, Cadge W, Gage EA, et al: The religious and spiritual beliefs and practices of academic pediatric oncologists in the United States. *J Pediatr Hematol Oncol* 29:736–742, 2007.

The religious and spiritual beliefs of pediatric oncologists were compared with those of the general public, because it is recognized that religion and spirituality are important to the care of seriously ill patients. Many oncologists described themselves as spiritual, while also reporting that they did not have a religious identity.

160. Seale C: The role of doctors' religious faith and ethnicity in taking ethically controversial decisions during end-of-life care. *J Med Ethics* 36:677–682, 2010.

In this study the author compares ethnicity and religious faith in the medical and general United Kingdom populations and reports on their associations with ethically controversial decisions taken when providing care to dying patients. Based on the study's findings, the author advocates for greater acknowledgement of the relationship of doctors' values with clinical decision making.

164. Fagerlin A, Wang C, Ubel PA: Reducing the influence of anecdotal reasoning on people's health care decisions: is a picture worth a thousand statistics? *Med Decis Making* 25:398–405, 2005.

This study was designed to assess participants' decision making when given a quiz or pictograph versus anecdotal information and how heavily each was relied upon. The use and influence of anecdotal information decreased when participants were presented with statistical information in a pictograph.

165. Feigin RD: Prospects for the future of child health through research. *JAMA* 294:1373–1379, 2005.

Advances made possible through genomics, proteomics, and the application of nanosystem technology, coupled with a greater understanding of the influence of the environment on human genes, will enhance our ability to prevent, modify, or cure numerous childhood disorders. This article reviews some of the more pressing and important causes of morbidity and mortality in children, discusses the manner in which some of the newer technologies may be applied to investigations of these disorders, and offers predictions concerning the effect that new discoveries may have in ameliorating the morbid consequences of childhood diseases. The author highlights the need to design and implement prospective long-term studies to determine the most effective ways to reduce the burden of preventable problems, which are rooted in societal issues.

172. Nowlan W: Human genetics. A rational view of insurance and genetic discrimination. *Science* 297:195–196, 2002.

The Human Genome Project has committed a portion of its annual budget to the study of the ethical, legal, and social implications (ELSI) of genetics research. The assertion that discrimination in health insurance is a real problem pervades the ELSI literature, despite compelling evidence that at worst the threat is theoretical. The author reviews this evidence and also argues that genetic discrimination in the area of life insurance is unlikely to become a significant social problem.

182. Howard SC, Pedrosa M, Lins M, et al: Establishment of a pediatric oncology program and outcomes of childhood acute lymphoblastic leukemia in a resource-poor area. *JAMA* 291:2471–2475, 2004.

The cure rate for childhood acute lymphoblastic leukemia (ALL) differs markedly between developed and developing countries. The authors assess the effect of a multidisciplinary team approach and protocol-based therapy on the event-free survival of children with ALL in an area with limited resources over 22 years. The 5-year event-free survival improved steadily with implementation of a range of changes over time. The authors conclude that the treatment of childhood ALL in a dedicated pediatric oncology unit using a comprehensive multidisciplinary team approach, protocol-based therapy, and local support and funding is associated with improved outcomes in a resource-poor area.

185. Glickman SW, McHutchison JG, Peterson ED, et al: Ethical and scientific implications of the globalization of clinical research. *N Engl J Med* 360:816–823, 2009.

Economic globalization is an important development of the past half century. The authors address several important questions related to this development. Who benefits from the globalization of clinical trials? What is the potential for exploitation of research subjects? Are trial results accurate and valid, and can they be extrapolated to other settings? In this article, they discuss recent trends in and underlying reasons for the globalization of clinical research, highlight important scientific and ethical concerns, and propose steps for the harmonization of international clinical research.

188. Pasquali SK, Burstein DS, Benjamin DK, et al: Globalization of pediatric research: analysis of clinical trials completed for pediatric exclusivity. *Pediatrics* 126:e687–e692, 2010.

This study was conducted to assess the setting in which pediatric research is conducted and its influence in the globalization of pediatric research. Studies under the U.S. Pediatric Exclusivity Provision were included that reported trial data between 1998 and 2007. Fifty-four countries were represented in conducting pediatric research, and the majority of published research was conducted at locations outside the United States.

APPENDICES

Reference Values in Infancy and Childhood

Carlo Brugnara

APPENDIX 1 Hematologic Values* in Normal Fetuses at Different Gestational Ages

Week of Gestation	Hemoglobin (g/dL)	RBCs ($\times 10^6$/mL)	Hematocrit (%)	Mean Corpuscular Volume (fL)	Total WBCs ($\times 10^6$/μL	Corrected WBCs ($\times 10^6$/μL)	Platelets ($\times 10^6$/μL)
18-21 (N = 760)	11.69 ± 1.27	2.85 ± 0.36	37.3 ± 4.32	131.1 ± 11.0	4.68 ± 2.96	2.57 ± 0.42	234 ± 57
22-25 (N = 1200)	12.2 ± 1.6	3.09 ± 0.34	38.59 ± 3.94	125.1 ± 7.8	4.72 ± 2.82	3.73 ± 2.17	247 ± 59
26-29 (N = 460)	12.91 ± 1.38	3.46 ± 0.41	40.88 ± 4.4	118.5 ± 8.0	5.16 ± 2.53	4.08 ± 0.84	242 ± 69
>30 (N = 440)	13.64 ± 2.21	3.82 ± 0.64	43.55 ± 7.2	114.4 ± 9.3	7.71 ± 4.99	6.4 ± 2.99	232 ± 87

Modified from Forestier F, Daffos F, Catherine N, et al: Developmental hematopoiesis in normal human fetal blood. Blood *77:2360, 1991.*
RBCs, Red blood cells; *WBCs,* white blood cells.
*Hematologic data obtained with a Coulter S plus II instrument. Total WBC count included nucleated red blood cells. Corrected WBC count included only WBCs, after subtracting the nucleated red cell component, based on a 100-cell manual differential.

APPENDIX 2 WBC Manual Differential Counts in Normal Fetuses at Different Gestational Ages

Week of Gestation	Lymphocytes (%)	Neutrophils (%)	Eosinophils (%)	Basophils (%)	Monocytes (%)	Nucleated RBCs (% of WBCs)
18-21 (N = 186)	88 ± 7	6 ± 4	2 ± 3	0.5 ± 1	3.5 ± 2	45 ± 86
22-25 (N = 230)	87 ± 6	6.5 ± 3.5	3 ± 3	0.5 ± 1	3.5 ± 2.5	21 ± 23
26-29 (N = 144)	85 ± 6	8.5 ± 4	4 ± 3	0.5 ± 1	3.5 ± 2.5	21 ± 67
>30 (N = 172)	68.5 ± 15	23 ± 15	5 ± 3	0.5 ± 1	3.5 ± 2	17 ± 40

From Forestier F, Daffos F, Catherine N, et al: Developmental hematopoiesis in normal human fetal blood. Blood *77:2360, 1991.*
RBCs, Red blood cells; *WBCs,* white blood cells.

APPENDIX 3 Hematologic Values for Cord Blood (Vaginal Delivery and Cesarean Section*)

	Study Sample (N = 167)		**Vaginal Delivery (N = 63)**		**Cesarean Section (N = 104)**		
Characteristic	Median	Range	Median	Range	Median	Range	**P-value[2]**
WBC ($\times10^9$ per l)	15.1	5.54-39.7	18.4	12.0-34.1	13.6	8.54-39.7	<0.0001
RBC ($\times10^{12}$ per l)	4.7	3.46-6.62	4.78	3.89-6.30	4.62	3.46-6.62	NS
Hb (g l^{-1})	174	130-234	176	140-230	171	130-234	NS
Hct (%)	53.6	40.1-73.1	54.7	41.9-73.1	52.6	40.1-72.2	NS
MCV (fl)	112	97.7-127	114	105-127	112	97.7-125	NS

From Eskola M, Juutistenaho S, Aranko K, et al: J Perinatol *2011; 258–262. Data obtained with Sysmex K-1000 analyzer (Sysmex, Kobe Japan).*

Hb, Hemoglobin; *Hct,* hematocrit; *MCH,* mean corpuscular hemoglobin; *MCHC,* mean corpuscular hemoglobin concentration; *MCV,* mean corpuscular volume; *MPV,* mean platelet volume; *NS,* not significant; *plateletcrit,* MPV × PLT; *PLT,* platelet; *RBC,* red blood cell; *RDW,* red blood cell distribution width; *WBC,* white blood cell.

*aP-values of the differences between vaginal delivery and cesarean section. The concentrations were standardized to exclude the varying effect of the anticoagulant.

APPENDIX 4 Hematologic Values* for Normal Cord Blood

	Mean ± SD		**Mean ± SD**
Red Blood Cells		% HYPER (MCHC >41 g/dL)	0.6 ± 0.3
Hb (g/dL)	15.3 ± 1.3	% MICRO (MCV <61 fL)	0.8 ± 0.3
Hct (%)	49 ± 5	% MACRO (MCV >120 fL)	31.8 ± 9.7
RBC ($\times10^6/\mu$L)	4.3 ± 0.4	**Reticulocytes**	
MCV (fL)	112 ± 6	%	3.63 ± 1.11
MCH (pg)	36.2 ± 2.2	Absolute reticulocytes ($\times10^9$/L)	156.1 ± 47.7
MCHC (g/dL)	30.9 ± 1.3	MCVr (fL)	125.8 ± 7.3
CHCM (g/dL)	30.4 ± 1.2	CHCMr (g/dL)	25.6 ± 1.2
% HYPO (MCHC <28 g/dL)	17.3 ± 11.9	CHr (pg)	31.3 ± 1.4

Modified from Diagne I, Archambeaud MP, Diallo D, et al: Parametres erythrocytaires et reservés en fer dans le sang du cordon. Arch Fr Pediatr *2:208, 1995; and from G Tchernia, personal communication. Data obtained in 142 specimens with H*2 Technicon analyzer.*

CHCM, Cell hemoglobin concentration mean; *CHCMr,* reticulocyte cell hemoglobin concentration mean; *CHr,* reticulocyte hemoglobin content; *Hb,* hemoglobin; *Hct,* hematocrit; *% HYPER,* % hyperchromic red cells; *% HYPO,* % hypochromic red cells; *% MACRO,* % macrocytic red cells; *MCH,* mean corpuscular hemoglobin; *MCHC,* mean corpuscular hemoglobin concentration; *MCV,* mean corpuscular volume; *MCVr,* reticulocyte mean corpuscular volume; *% MICRO,* microcytic red cells; *RBC,* red blood cell; *SD,* standard deviation.

*Values obtained with Technicon H*2 and H*3 Hematology analyzers (Bayer Diagnostics) in neonates delivered at term with weight ≥2500 g.

APPENDIX 5 Red Cell and Reticulocyte Indices, Serum Iron Status Markers in Cord Blood

Parameter	Mean	SD	Reference Range*
Blood Count and Cellular Indices

Serum Measurements			
TfR, mg/L	2.0	0.7	1.2-4.0
Ferritin, µg/L	198	137	45-636
TfR-F index	0.95	0.43	0.49-2.1
Iron, µmol/L	27.4	7.7	12.2-42.1
Transferrin, g/L	2.0	0.4	1.2-2.9
TfSat, %	55	19	21-111

From Ervasti M, Kotisaari S, Sankilampi U, et al: The relationship between red blood cell and reticulocyte indices and serum markers of iron status in the cord blood of newborns. Clin Chem Lab Med *45:1000–1003, 2007. Hematologic data obtained in 199 full-term newborn infants with a ADVIA 120 analyzer (Siemens Diagnostic Solutions, Terrytown, NY).*

CHm, Cellular hemoglobin in red blood cells; *CHr,* cellular hemoglobin in reticulocytes; *Hb,* hemoglobin; *HCT,* hematocrit; *%HYPOm,* percentage of hypochromic red blood cells; *%HYPOr,* percentage of hypochromic reticulocytes; *IRF-H,* high immature reticulocyte fraction; *MCH,* mean cell hemoglobin; *MCHC,* mean cell hemoglobin concentration; *MCV,* mean cell volume of red blood cells; *MCVr,* mean cell volume of reticulocytes; *%Retic,* proportion of reticulocytes; *TfR,* transferrin receptor; *TfR-F* index, transferrin receptor/log (ferritin); *TfSat,* transferrin saturation.

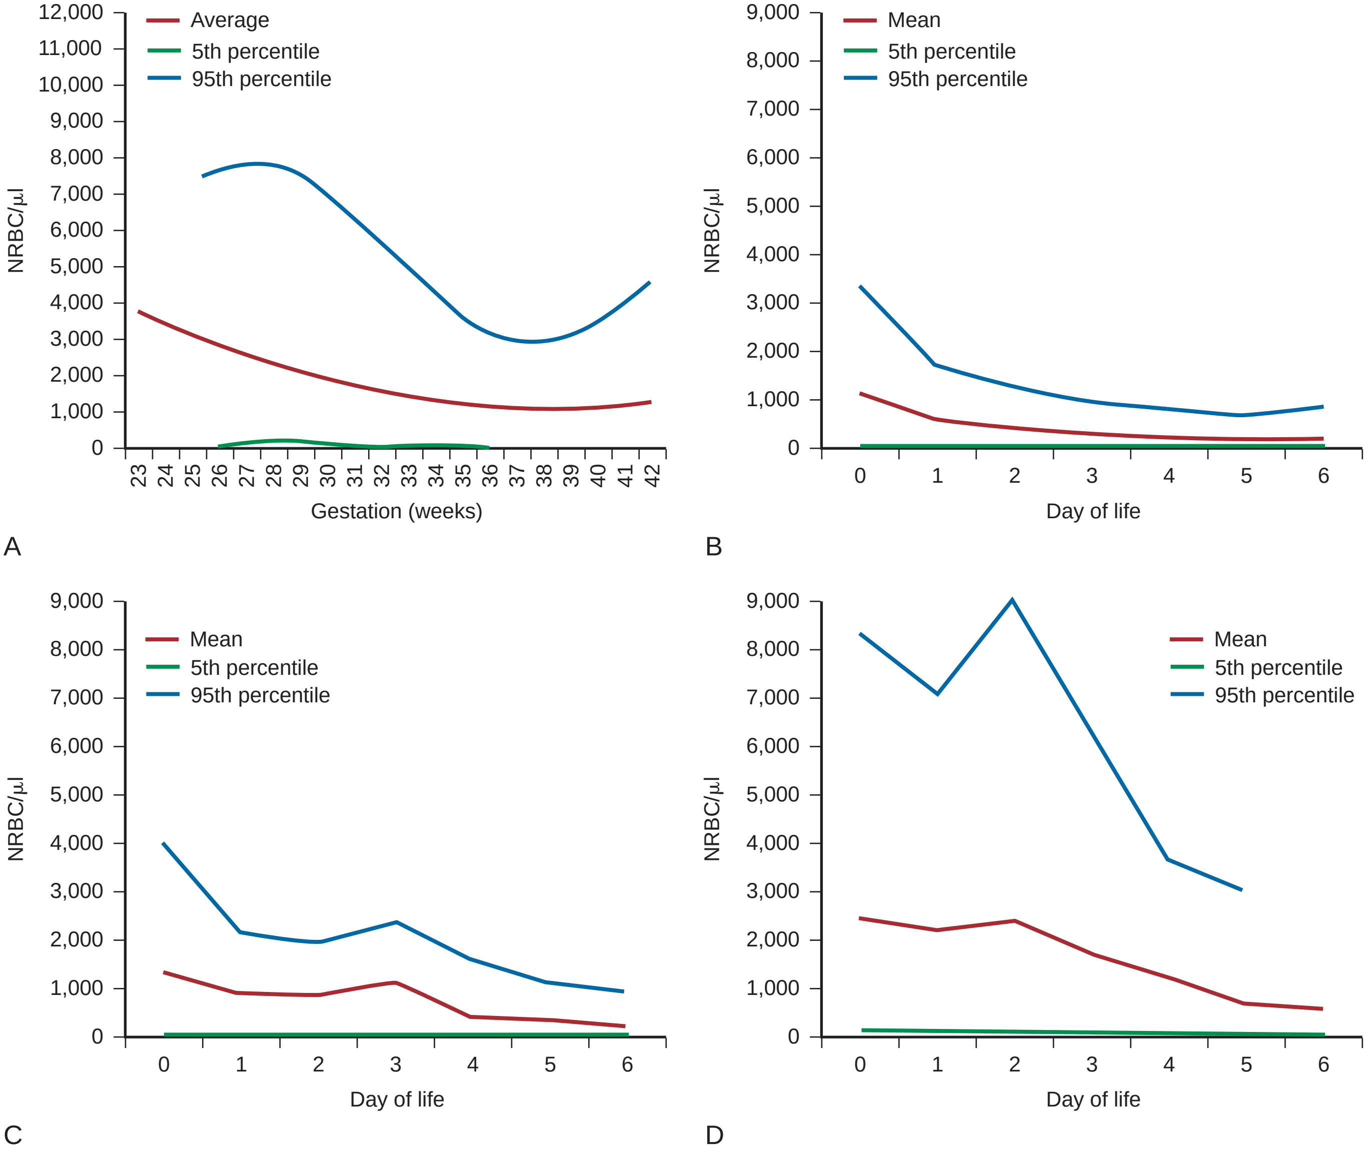
*For reference range calculations, only samples in which Hb was greater than 146 g/L were included.

APPENDIX 6 Erythroblast and Leukocyte Counts in Umbilical Cord Blood*

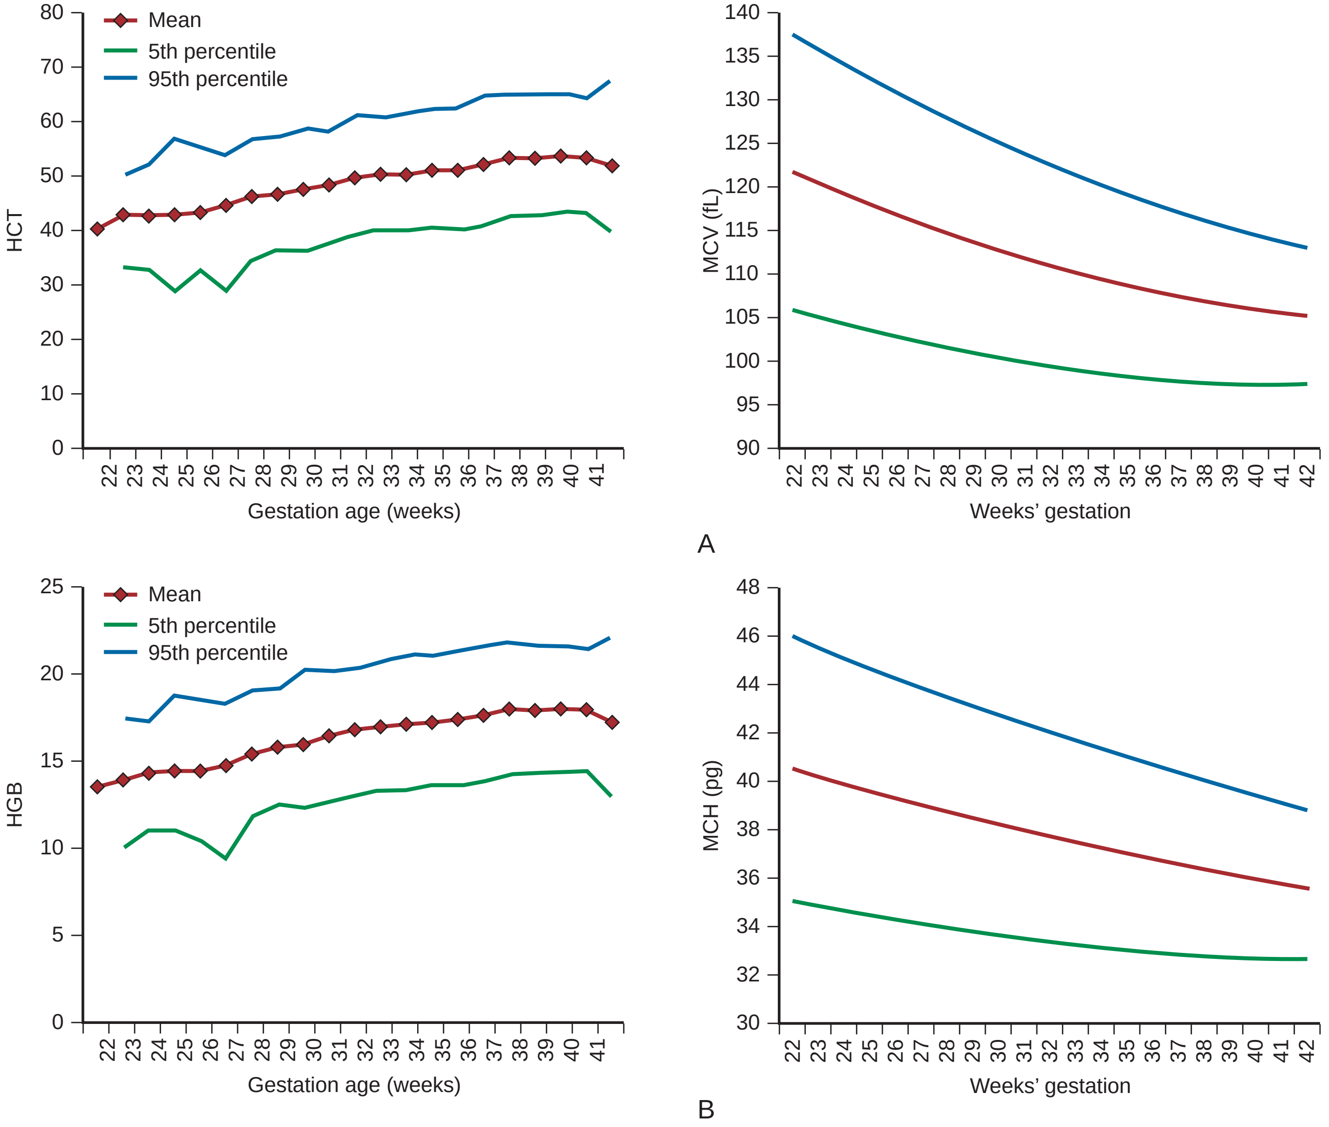
Type of Delivery	Erythroblast Count (×10⁹/L)	Leukocyte Count (×10⁹/L)
Spontaneous, vaginal (N = 55)	0.75 (0.0-5.3)	13.8 (7.25-48.0)
Elective cesarean section (N = 39)	0.30 (0.0-0.49)	10.6 (6.2-17.7)
Emergency cesarean section (N = 55)	1.10 (0.0-15.9)	13.5 (4.2-40.3)

From Thilaganthan B, Athansasiou S, Ozmen S, et al: Umbilical cord blood erythroblast count as an index of intrauterine hypoxia. Arch Dis Child *70:F192, 1994.*

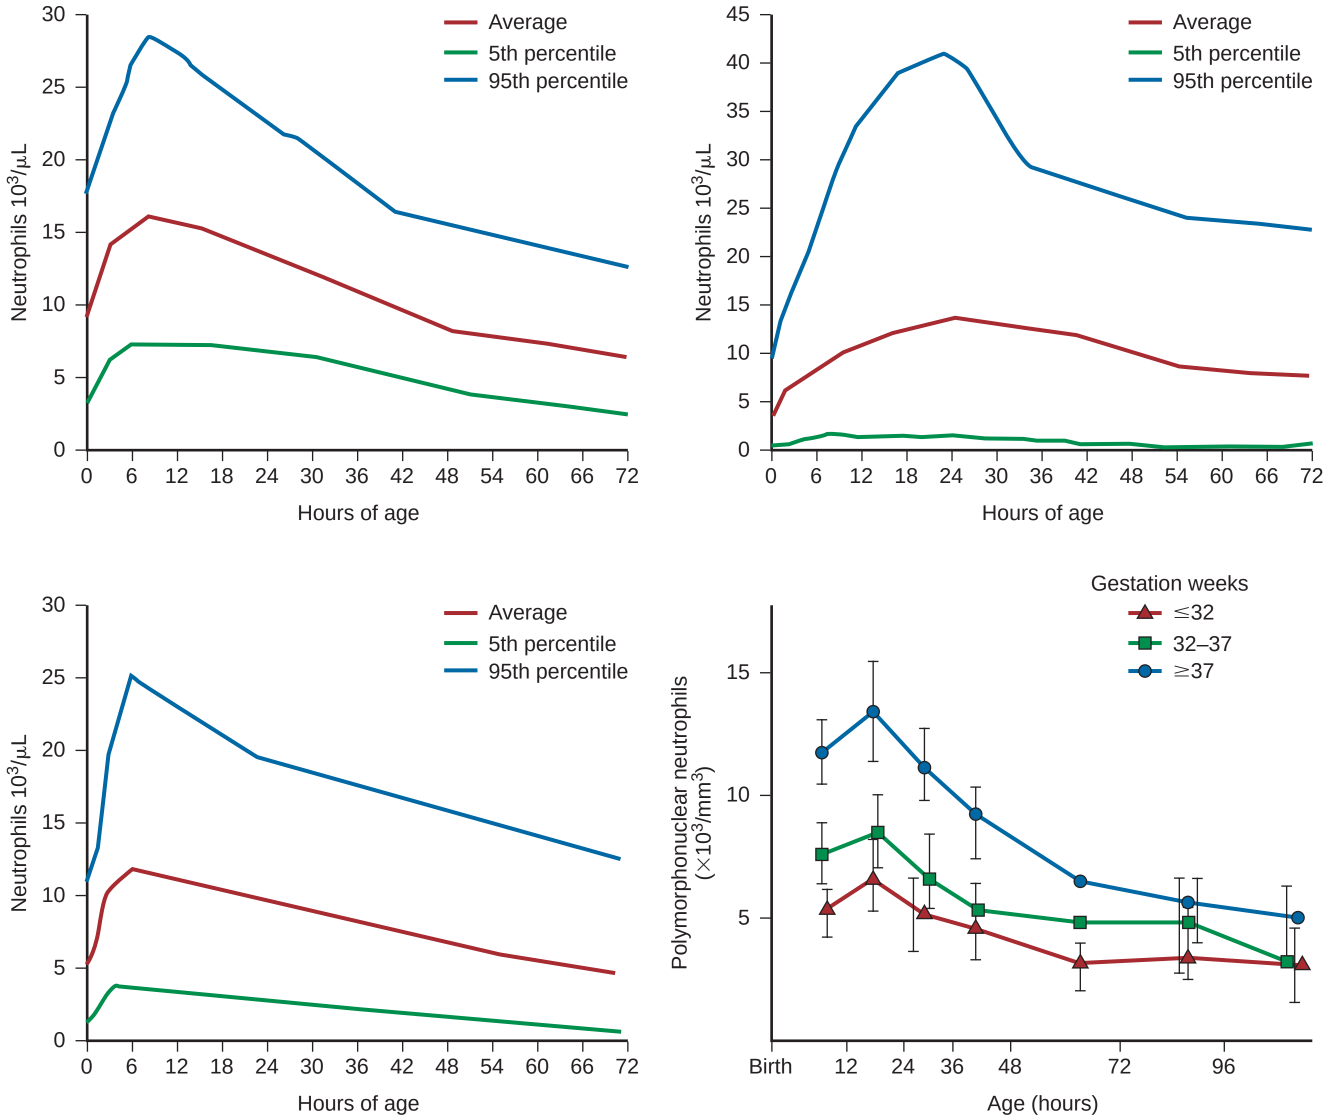
*Values are expressed as mean (range). Erythroblast counts were significantly higher in the spontaneous vaginal and emergency cesarean section groups compared with the elective cesarean group.



Appendix 7 **A**, Reference ranges for blood concentrations of NRBC on the day of birth are displayed according to gestational age. The lower and upper lines represent the 5% and 95% limits, and the middle line represents the mean value. **B-D**, Reference ranges for blood concentrations of NRBC during the first 7 days following birth are shown. The lower and upper lines represent the 5% and 95% limits, and the middle line represents the mean value. **B**, Reference range for neonates 1 to 36 weeks' gestation at birth. **C**, Range for neonates 30 to 35 weeks' gestation at birth. **D**, Range for neonates 1 to 30 weeks' gestation at birth. *(From Christensen RD, Henry E, Andres RL et al. Reference ranges for blood concentrations of nucleated red blood cells in neonates.* Neonatol *99:289–294, 2011.)*



Appendix 8 *Left Column*, Reference ranges (5th percentile, mean, and 95th percentile) for hematocrits *(top)*, Hemoglobin *(bottom)*, both obtained during the first 6 hours after birth among patients 22 to 42 weeks gestation. *Right Column (top and bottom)*, Expected range of values for mean corpuscular volume (MCV, *a*) and mean corpuscular hemoglobin (MCH, *b*) for neonates on the first day after birth. The upper and lower boundaries incorporate 95% of the measured values. *(Left column, From Christensen RD, Henry E, Jopling J, et al: The CBC: reference ranges for neonates.* Semin Perinatol *33:3–11, 2009; Right column, From Christensen RD, Jopling J Henry E et al. The erythrocyte indices of neonates, defined using data from over 12000 patients in a multihospital health care system.* J Perinatol *28:24–28, 2008.)*



Appendix 9 *Top Left,* Reference ranges for blood neutrophil concentrations during the first 72 hours after the birth of term and near-term (36 weeks' gestation) neonates. A total of 12149 values were obtained for the analysis. The 5th percentile, the mean, and the 95th percentile values are shown. *Bottom Left,* Reference ranges for blood neutrophil concentration during the first 72 hours after the birth of 28 to 36 weeks' gestation preterm neonates. A total of 8896 values were obtained for the analysis. The 5th percentile, the mean, and the 95th percentile values are shown. *Top Right,* Reference ranges for blood neutrophil concentration during the first 72 hours after the birth of 28 weeks' gestation preterm neonates. A total of 852 values were obtained for the analysis. The 5th percentile, the mean, and the 95th percentile values are shown. *Bottom right,* Changes in polymorphonuclear neutrophils after birth in three groups with different gestational ages. Total white blood cell (WBC) counts were obtained with a Coulter S analyzer; manual differential counts were performed on 200 nucleated cells. *(Top and Bottom Left and Top Right, From Christensen RD, Henry E, Jopling J, et al: The CBC: reference ranges for neonates.* Semin Perinatol *33:3–11, 2009; Bottom Right, Modified from Coulombel L, Dehan M, Tchernia G, et al: The number of polymorphonuclear leukocytes in relation to gestational age in the newborn.* Acta Paediatr Scand *68:709, 1979.)*

APPENDIX 10 Reference Ranges for Hb, HCt, Reticulocyte Parameters, and S-TfR During the First 15 Weeks of Life

15.0	55.3	6.9	444.8	37.0	7.5	182.9

From Mäkela E, Takal TI, Suomine P, et al: Hematologic parameters in preterm infants from birth to 16 weeks of age with reference to iron balance. Clin Chem Lab Med *46:551–557, 2008. Ferritin assayed with Elecsys ferritin electrochemiluminescence immunoassay on a Modular E analyzer (Roche Diagnostics).*

*The information under the column "Ferritin" shows values calculated for the neonates who had not been transfused during the preceding 2 weeks of measurements. The information under the column "Ferritin, no transfusions" shows the values calculated for those neonates who had not been transfused at all (indicating ferritin level development in the most stable preterm neonates).

APPENDIX 12 Reference Ranges for CBC, Reticulocytes, Ferritin, and S-TfR During the First Year of Life in Preterm and Full-Term Infants

From Takale TI, Mäkela E, Suomine P, et al: Blood Cell and iron status analytes of preterm and full-term infants from 20 weeks onward during the first year of life. Clin Chem Lab Med *48:1295–1301, 2010. Hematologic data obtained with ADVIA 120, Siemens Medical Solutions, Tarrytown, NY. S-TfR measured with an automated immunoturbidimetric methos (IDeA sTfR-IT, Orion Diagnostica), Espoo, Finland. Ferritin assayed with Elecsys ferritin electrochemiluminescence immunoassay on a Modular E analyzer (Roche Diagnostics).*

CBC, Complete blood count; *CHr*, reticulocyte hemoglobin content; *Hb*, hemoglobin; *Hct*, hematocrit; *MCH*, mean corpuscular hemoglobin; *MCV*, mean corpuscular volume; *RBC*, red blood cell; *Retic*, reticulocyte; *RI*, reference interval; *S-Tfr*, soluble transferrin receptor; *WBC*, white blood cell.

From Lim EM, Cembrowski G, Cembrowski M, et al: Race-specific WBC and neutrophil count reference intervals. J Lab Clin Hematol *32:590–597, 2010.*
ANC, Absolute neutrophil count; *MAF,* female Mexican American; *MAM,* male Mexican American; *NHBF,* female non-Hispanic black; *NHBM,* male non-Hispanic black; *NHWF,* female non-Hispanic white; *NHWM,* male non-Hispanic white; *WBC,* white blood cell.
[*] Data are presented as reference intervals (2.5-97.5 percentile limits) and mean values (in parentheses).
[†] Could not be pooled because of variation within and between populations.

APPENDIX 18 Activities of RBC Enzymes

Enzyme	**Activity at 37° C (mean ± SD)**
Acetylcholinesterase	36.93 ± 3.83
Adenosine deaminase	1.11 ± 0.23
Adenylate kinase	258 ± 29.3
Aldolase	3.19 ± 0.86
Bisphosphoglyceromutase (2,3- diphosphoglyceromutase)	4.78 ± 0.65
Catalase	$15.3 \pm 2.4 \times 10^4$
Enolase	5.39 ± 0.83
Epimerase	0.23 ± 0.06
Galactokinase	0.029 ± 0.004
Galactose-1-phosphate uridyltransferase	28.4 ± 6.94
Glucose phosphate isomerase	60.8 ± 11.0
Glucose-6-phosphate dehydrogenase	8.34 ± 1.59
WHO method	12.1 ± 2.09
Glutamic oxaloacetic transaminase without PLP	3.02 ± 0.67
Glutamic oxaloacetic transaminase with PLP	5.04 ± 0.90
γ-Glutamylcysteine synthetase	0.43 ± 0.04
Glutathione peroxidase	30.82 ± 4.65
Glutathione reductase without FAD	7.18 ± 1.09
Glutathione reductase with FAD	10.4 ± 1.50
Glutathione S-transferase	6.66 ± 1.81
Glyceraldehyde phosphate dehydrogenase	226 ± 41.9
Hexokinase	1.78 ± 0.38
Hypoxanthine phosphoribosyltransferase	1.72 ± 0.30
Lactate dehydrogenase	200 ± 26.5
Methemoglobin reductase	2.60 ± 0.71
Monophosphogylceromutase	37.71 ± 5.56
NADH-methemoglobin reductase	19.2 ± 3.85 (30°)
NADPH diaphorase	2.26 ± 0.16
Phosphofructokinase	11.01 ± 2.33
Phosphoglucomutase	5.50 ± 0.62
Phosphoglycerate kinase	320 ± 36.1
Phosphoglycolate phosphatase	1.23 ± 0.10
Pyrimidine 5' nucleotidase	0.11 ± 0.03
Pyruvate kinase	15.0 ± 1.99
6-Phosphogluconate dehydrogenase	8.78 ± 0.78
Triose phosphate isomerase	2111 ± 397

SD, Standard deviation.

APPENDIX 20 Red Cell Enzyme Activity in Premature and Term Neonates, Adults, and Adult Reticulocytes

	Premature Infants (N = 11)	Term Infants (N = 10)	Normal Adults (N = 50)	95% Adult* Reticulocytes
Hexokinase (HK)	3.6 ± 0.6[a]	2.7 ± 0.3[a]	1.15 ± 0.35	9.9[a]
Glucosephosphate isomerase (PGI)	94.5 ± 15.2[a]	88 ± 16[a]	67.7 ± 12.0	95.7[c]
Phosphofructokinase (PFK)	8.0 ± 1.3[d]	7.1 ± 1.5[c]	8.4 ± 3.4	14.1[d]
Aldolase (ALD)	4.3 ± 0.8[c]	5.3 ± 1.7[b]	3.55 ± 1.07	9.5[a]
Triosephosphate isomerase (TIM)	2961 ± 1378[d]	1787 ± 380[d]	2700 ± 700	3220[d]
Glyceraldehyde-3-phosphate dehydrogenase (GAPDH)	131 ± 76[d]	164 ± 45[d]	134 ± 93	240[d]
Phosphoglycerate mutase (PGK)	591 ± 114[b]	436 ± 119[b]	312 ± 86	438[d]
Diphosphoglycerate mutase (DPGM)	8.3 ± 3.6[c]	6.7 ± 1.9[c]	5.3 ± 2.5	7.3[d]
Enolase (ENO)	15.1 ± 3.4[a]	14.6 ± 2.1[a]	7.8 ± 2.2	8.1[d]
Pyruvate kinase (PK)	19.4 ± 3.5[a]	17.3 ± 2.5[a]	11.4 ± 2.8	54.2[a]
Glucose-6-phosphate dehydrogenase (G6PD)	21.3 ± 3.8[a]	19.1 ± 4.3[a]	10.9 ± 3.8	30.6[a]
6-Phosphogluconate dehydrogenase (6PGD)	9.1 ± 2.1[d]	9.9 ± 1.6[c]	8.4 ± 1.0	14.4[a]
Glutathione reductase (GR)	9.5 ± 1.7[a]	11.0 ± 2.6[a]	7.2 ± 2.2	11.3[c]
Acetyl choline esterase (ACE)	17.5 ± 3.5[a]	18.5 ± 4.1[a]	36.9 ± 3.8	44.4[c]

From Jansen G, Koenderman L, Rijksen G, et al: Characteristics of hexokinase, pyruvate kinase, and glucose-6-phosphate dehydrogenase during adult and neonatal reticulocyte maturation. Am J Hematol *20:203–215, 1985.*

*Obtained after Percoll density gradient centrifugation of red cells from a patient with a hemolytic syndrome. Statistical interpretation versus normal adult group: [a]*P* <.001; [b]*P* <.01; [c]*P* <.1; [d]not significant.

APPENDIX 21 Red Cell Glycolytic Intermediate Metabolites in Normal Adults, Term Infants, and Premature Infants*

Metabolite	**Normal Adults (10)**	**Term Infants (10)**	**Premature Infants (11)**	**Normals (5)**
Glucose-6-phosphate	24.8 ± 9.8	45.2 ± 8.7	66.8 ± 34.8	27 ± 2.4
Fructose-6-phosphate	5.4 ± 1.0	9.9 ± 2.3	20.5 ± 8.9	11 ± 2.5
Fructose, 1,6-diphosphate	4.6 ± 1.0	3.8 ± 0.7	3.6 ± 0.8	5 ± 0.9
Dihydroxyacetone phosphate	4.9 ± 3.5	11.9 ± 5.0	18.6 ± 10.7	12 ± 3.7
Glyceraldehyde-3-phosphate	2.6 ± 0.7	1.9 ±1.6	6.5 ± 3.2	4 ± 1.5
3-Phosphoglycerate	61.6 ± 12.4	58.2 ± 14.4	47.5 ± 14.2	48 ± 16.1
2-Phosphoglycerate	4.3 ± 1.8	4.9 ± 1.6	4.4 ± 2.5	7 ± 1.7
Phosphoenolpyruvate	8.8 ± 2.6	7.6 ± 2.9	7.4 ± 3.0	12 ± 0.9
Pyruvate	73.5 ± 33.1	70.4 ± 32.3	78.4 ± 4.15	71 ± 17.7
2,3-Diphosphoglycerate	4423 ± 1907	3609 ± 800	3152 ± 2133	4000

From Oski FA: Red cell metabolism in the newborn infant: V. Glycolytic intermediates and glycolytic enzymes. Pediatrics *44:87, 1969.*

*Infant samples were obtained from newborns weighing more than 2800 g whose gestational age was 39 weeks or greater. Blood was drawn within 24 hours of birth. All the newborns were clinically healthy. Adult samples were obtained from healthy normal volunteers.

APPENDIX 22 RBC Enzyme Activity* in ELBWI Infants and Premature and Normal Adults (Whole Blood and Reticulocyte Rich)

	Normal Adult (N = 28) Mean ± SD	**ELBWI (N = 28) Mean ± SD**	**Reticulocyte Rich (N = 20) Mean ± SD**	**ELBWI Versus Reticulocyte Rich**	**ELBWI Versus Normal Adults**
Hexokinase (HK)	1.05 ± 0.11	3.28 ± 0.47	3.45 ± 1.78	NS	High (*P* <.0001)
Glucosephosphate isomerase (GPI)	58.4 ± 5.0	83.4 ± 6.2	65.2 ± 8.5	High (*P* <.0001)	High (*P* <.0001)
Phosphofructokinase (PFK)	13.3 ± 1.7	10.1 ± 1.6	15.8 ± 2.4	Low (*P* <.0001)	Low (*P* <.0001)

Triosephosphate isomerase (TPI)	1760 ± 253	2215 ± 339	2077 ± 375	NS	High (*P* <.0001)
Glyceraldehyde-3-phosphate dehydrogenase (GA3PD)	191 ± 34	252 ± 39	232 ± 51	NS	High (*P* <.0001)
Phosphoglycerate kinase (PGK)	288 ± 31	469 ± 67	355 ± 43	High (*P* <.0001)	High (*P* <.0001)
Monophosphoglycerate mutase (MPGM)	23.5 ± 2.8	33.8 ± 6.9	29.9 ± 5.3	High (*P* = .0412)	High (*P* <.0001)
Enolase (ENL)	6.9 ± 1.0	23.9 ± 3.0	9.3 ± 1.7	High (*P* <.0001)	High (*P* <.0001)
Pyruvate kinase (PK)	16.3 ± 2.1	29.7 ± 4.0	27.6 ± 8.1	NS	High (*P* <.0001)
Lactate dehydrogenase (LDH)	195 ± 17	248 ± 28	264 ± 34	NS	High (*P* <.0001)
Glucose-6-phosphate dehydrogenase (G6PD)	7.6 ± 0.8	18.1 ± 2.2	12.8 ± 2.0	High (*P* <.0001)	High (*P* <.0001)
6-Phosphogluconate dehydrogenase (6PGD)	8.1 ± 1.0	8.2 ± 1.5	13.2 ± 1.8	Low (*P* <.0001)	NS
Glutathione reductase (GR)	7.1 ± 1.2	9.2 ± 1.8	7.8 ± 1.8	High (*P* = .0090)	High (*P* <.0001)
GR + flavin adenine dinucleotide (FAD)	9.9 ± 1.6[b]	10.9 ± 1.7[b]	10.4 ± 1.7	NS	NS
Glutathione peroxidase (GSH-Px)	31.8 ± 5.7	22.5 ± 4.0	41.3 ± 7.4	Low (*P* <.0001)	Low (*P* <.0001)
Adenylate kinase (AK)	252 ± 35	132 ± 18	253 ± 26	Low (*P* <.0001)	Low (*P* <.0001)
Adenosine deaminase (ADA)	1.25 ± 0.33	0.96 ± 0.30	1.60 ± 0.60	Low (*P* <.0001)	Low (*P* = .0010)
Acetylcholinesterase (AchE)	31.7 ± 4.7	16.7 ± 3.3	37.6 ± 10.1	Low (*P* <.0001)	Low (*P* <.0001)
Pyrimidine 5'-nucleotidase	9.1 ± 1.4	17.0 ± 4.0	19.1 ± 4.5	ns	High (*P* <.0001)
NADH methemoglobin reductase (MetHbR)	14.9 ± 1.8[b]	11.5 ± 2.1[a]	14.1 ± 2.3[a]	Low (*P* = .0087)	Low (*P* <.0001)
Catalase (CAT)	13.6 ± 2.1[b]	11.8 ± 2.7[a]	15.6 ± 3.2[a]	Low (*P* = .0048)	Low (*P* = .0459)
Reduced glutathione (GSH) (mg/dL RBC)	67.8 ± 9.3	76.9 ± 13.8	69.4 ± 12.0	NS	High (*P* = .0059)

From Miyazono Y, Hirono A, Miyamoto Y, et al: Erythrocyte enzyme activities in cord blood of extremely low-birth-weight infants. Am J Hematol *62:88–92, 1999.*

ELBWI, Extremely low-birth-weight infants (birth weight <1000 g); *Hb*, hemoglobin; *NS*, not significant; *RBC*, red blood cell; *SD*, standard deviation.

*All enzyme activities are represented as units/g Hb, except for CAT (10^4 units/g Hb) and P5N (μmol Pi liberated/hr/g Hb). [a]N = 12; [b]N = 20.

APPENDIX 23 G6PD Reference Values for G6PD-Normal and –Deficient Males and Females with Probable Genotypes

Category (U/g Hb)	No.	Median Value	IQR	Min-Max	G6PD Phenotype	Probable Genotype*†
Male (N = 1502)						
<7.0	243 (16.2%)	0.28	0.21-0.39	0.01-6.20	Deficient	Deficient hemizygote
≥9.0	1256 (83.8%)	18.76	17.27-21.68	9.00-34.66	Normal	Normal hemizygote
Female (N = 1298)						
<7.0	81 (6.2%)	4.84	0.45-6.16	0.06-6.96	Deficient	Deficient homozygote
7.0-9.4	64 (4.9%)	8.61	7.67-9.00	7.04-9.46	Intermediate	Heterozygote
≥9.5	1153 (88.8%)	18.36	16.21-20.63	9.54-35.50	Normal	Normal homozygote

*In females, because of nonrandom X chromosome inactivation among heterozygotes, accurate genotype categories may be difficult to determine based on phenotype. The term “probable” genotype is therefore used.

†Male genotype based on phenotype may be assumed with reasonable accuracy.

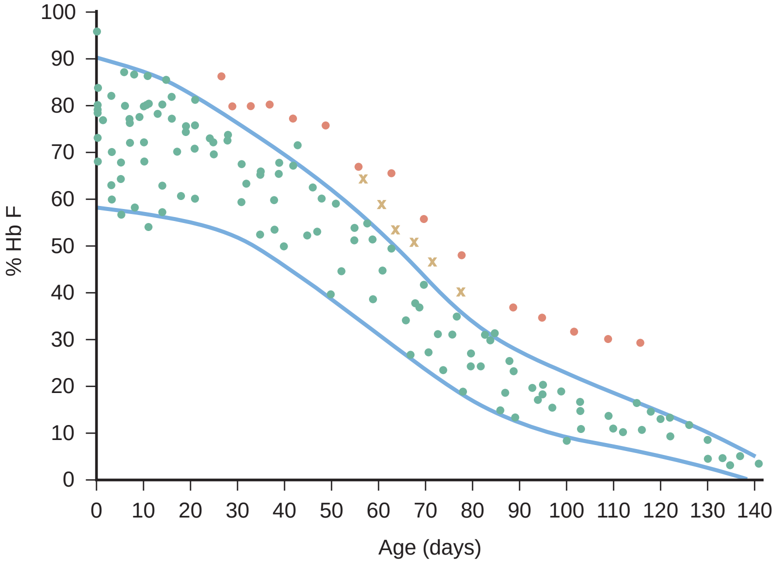
APPENDIX 24 Hemoglobin A Content in Male and Female Newborns According to Birth Weight

Birth Weight (g)	Males Hb A (%)	Females Hb A (%)
<1501	7.1 ± 1.3 (9)	13.2 ± 11.3 (14)
1501-2000	12.2 ± 8.2 (36)	13.1 ± 10.4 (44)
2001-2500	12.6 ± 5.2 (139)	14.9 ± 6.5 (206)*
2501-3000	15.8 ± 6.4 (635)	17.8 ± 6.2 (776)*
3001-3500	18.2 ± 6.5 (1289)	19.9 ± 6.8 (1204)*
3501-4000	20.0 ± 6.6 (803)	20.9 ± 7.2 (590)*
4001-4500	19.7 ± 6.3 (200)	22.6 ± 8.6 (94)*
>4500	21.7 ± 7.0 (45)	20.9 ± 7.2 (20)

From Galacteros F, Guilloud-Bataille M, Feingold J: Sex, gestational age, and weight dependency of adult hemoglobin concentration in normal newborns. Blood *78:1121, 1991.*

HbA, Hemoglobin A.

**P* <.05 between male and female newborns.



Appendix 25 Relative concentration of hemoglobin F in infants and its variation with age. The region between the curved lines contains 120 observations in 17 normal children. *(From Garby L, Sjolin S. Development of erythropoiesis.* Acta Paediatr *51:245, 1962.)*

APPENDIX 26 Percentage of Hemoglobins F and A2 in the Newborn and Adult*

	% Hb F (Gα:Aα ratio)	% Hb A2
Newborn	60-90 (3:1)	<1.0
Adult	<1.0 (2:3)	1.6-3.5

From Altman PL, Dittmer DS, editors: Human health and disease. *Bethesda, MD, 1977, Federation of American Societies for Experimental Biology, p. 159.*

Hb, Hemoglobin.

*The α chains of fetal hemoglobin contain either a glycyl residue or an alanyl residue at position 136. The Gα:Aα ratio in the newborn undergoes a considerable change between the third and fourth months of life, at which time it approximates that of the Hb F of adults.

APPENDIX 27 Methemoglobin Levels in Normal Children*

	METHEMOGLOBIN (g/dL)					METHEMOGLOBIN AS PERCENTAGE OF TOTAL HEMOGLOBIN

10-12	1.0	14.0	1.1	9.1
13-15	2.2	14.4	3.8	20.5
16-18	1.5	15.2	2.0	14.2

From Krafte-Jacobs B, Williams J,. Soldin SJ, Plasma erythropoietin reference ranges in children. J Pediatr *126:601, 1995.*

y, Years.

[*] Data obtained from a total of 1122 hospitalized and outpatient children ages 1 to 18 years. Levels found in anemic patients cannot be compared with normal values. In fact, as long as the erythropoietin-generating apparatus in the kidney is efficient, serum levels increase exponentially as the hematocrit concentration decreases. Serum erythropoietin must therefore be evaluated in relation to the degree of anemia, and every single laboratory should determine the exponential regression of serum erythropoietin versus hematocrit (or hemoglobin) in a home-made reference population of anemic subjects and define the 95% confidence limits. The patients gathered to calculate a reference regression equation should have an anemia with a single simple mechanism and no evidence of either renal failure or excessive cytokine production (i.e., normal values for C-reactive protein and α_2-globulins). Patients with chronic iron-deficiency anemia caused by nonneoplastic and noninflammatory chronic blood loss have the advantages of being easily found, unequivocably defined, and homogeneous. They could become the universal reference population, although patients with hemolytic anemia or thalassemia intermedia also may be studied as reference subjects. Serum erythropoietin levels are also much higher for hemoglobin concentration in hypoplastic than in hyperplastic states. Thus for the same hemoglobin concentration, serum erythropoietin levels are lower in thalassemia intermedia than in Diamond-Blackfan anemia.

APPENDIX 37 Membrane Lipid Composition of Fetal Erythrocytes

From Linderkamp O, Friederichs E, Meiselman HJ: Mechanical and geometrical properties of density-separated neonatal and adult erythrocytes. Pediatr Res *34:688–693, 1993.*

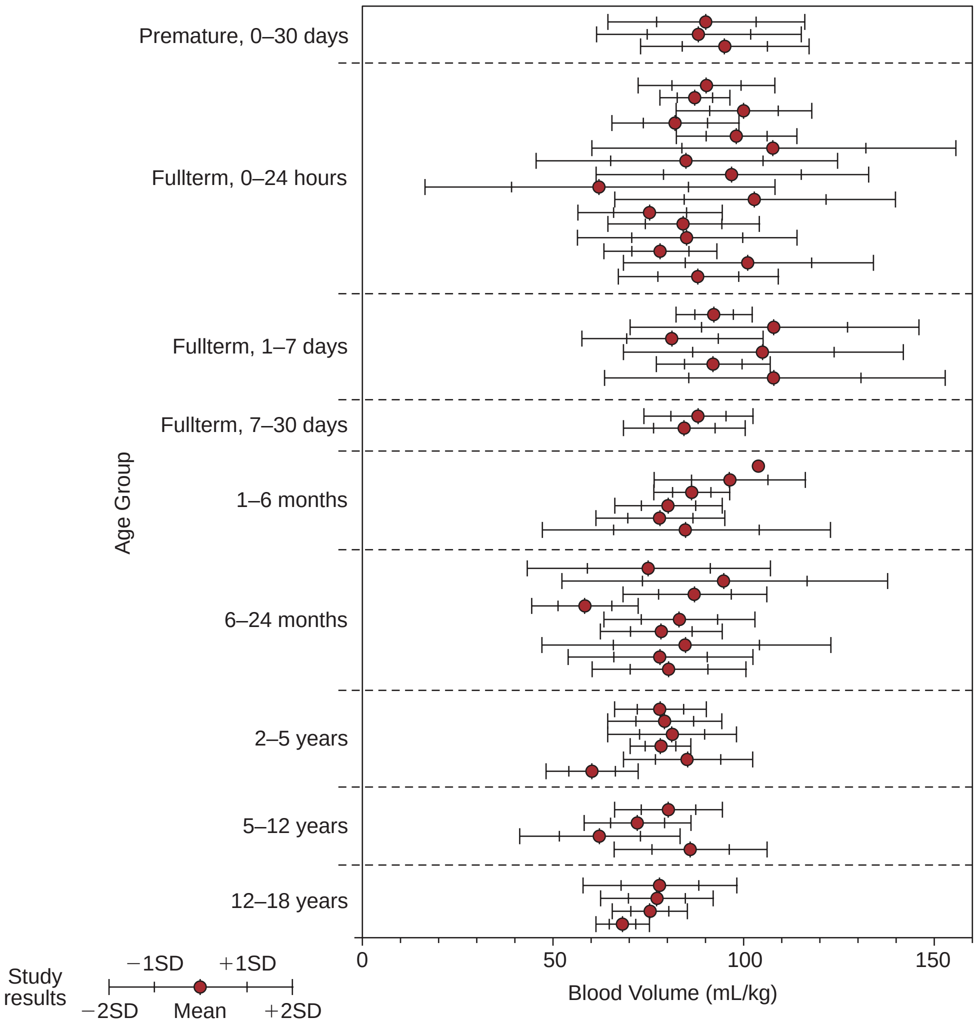
[*] Data are presented as mean ±SD for 10 nenonatal and 10 adult samples.

[†] Significant difference ($P < .05$ unpaired † test) between adult and neonatal erythrocytes.

[‡] Significant difference ($P < .05$ paired † test) between top or bottom fraction and unfractionated erythrocytes.

Age Group	No of Studies	Estimated Mean Circulating Blood Volume, mL/kg (95% CI)	Test of Homogeneity*	
			Q Statistic	*p*
All subjects	21	80.0 (77.4–82.5)	46.53	0.16
Premature newborns 0–30 d	3	91.5 (77.3–105.7)	0.18	0.91
Full-term newborns 0–24 h	16	87.7 (83.2–92.3)	11.69	0.70
Full-term newborns 1–7 d	6	91.7 (84.0–99.4)	2.40	0.79
Full-term newborns 7–30 d	2	86.0 (75.6–96.4)	0.09	0.76
Children 1–6 mo	6	84.0 (77.2–90.7)	2.68	0.75
Children 6–24 mo	9	75.4 (68.5–82.3)	8.74	0.36
Children 2–5 yr	6	75.7 (70.7–80.7)	7.26	0.20
Children 5 –12 yr	4	74.9 (67.3–82.6)	2.98	0.39
Children 12–18 yr	4	71.4 (66.2–76.5)	1.90	0.59

This compilation was obtained using study-level data from all studies.
*$p > .05$ indicates that results of the included studies are homogeneous and can be combined.



Appendix 39 Circulating blood volume by age group. Bars on the table indicate 1 and 2 standard deviations with the center point indicating study mean blood volume. *(From Riley AA, Arakawa Y, Worley S, et al. Circulating blood volumes: a review of measurement techniques and a meta-analysis in children.* ASAIO *56:260–264, 2010.)*

APPENDIX 40 Percentages and Absolute Counts for Total B cells and B-Cell Subsets*

	Number	Cord Blood	0-6 Months	6-12 Months	1-2 Years	2-3 Years	3-4 Years	4-6 Years	6-9 Years	9-12 Years	12-15 Years	15-18 Years

IG, Immunoglobulin; *RBE*, recent bone marrow emigrants.

*Total B cells (defined as CD19+ lymphocytes) as percentage of total lymphocytes. B-cell subsets as percentage of total B cells. Values are presented as medians (value range). Recent bone marrow emigrants were defined as CD19+IgD+CD10+ B cells, which brightly express CD38 and are CD27– and IgM+.

From van Gent R, van Tilburg CM, Nibbelke EE, et al: Refined characterization and reference values of the pediatric T- and B-cell compartments. Clin Immunol *133:95–107, 2009.*

Absolute counts × 10^6 per liter blood, unless stated differently. Values are presented as medians (value range). Counts of T-cell subsets in boldface, whereas counts of specific cell populations within these T-cell subsets in italics. *No.*, Number of individuals; *nd*, not determined.

sjTREC numbers × 10^6 per liter blood. Values are presented as medians (value range). *No.*, Number of individuals; *nd*, not determined. Naive = CD27$^+$CD45RO$^-$; memory = CD27$^+$CD45RO$^+$; effector = CD27$^-$CD45RO$^+$; *Treg* indicates regulatory T cells, which are defined as CD25$^+$CD127$^-$CD4$^+$ T cells.

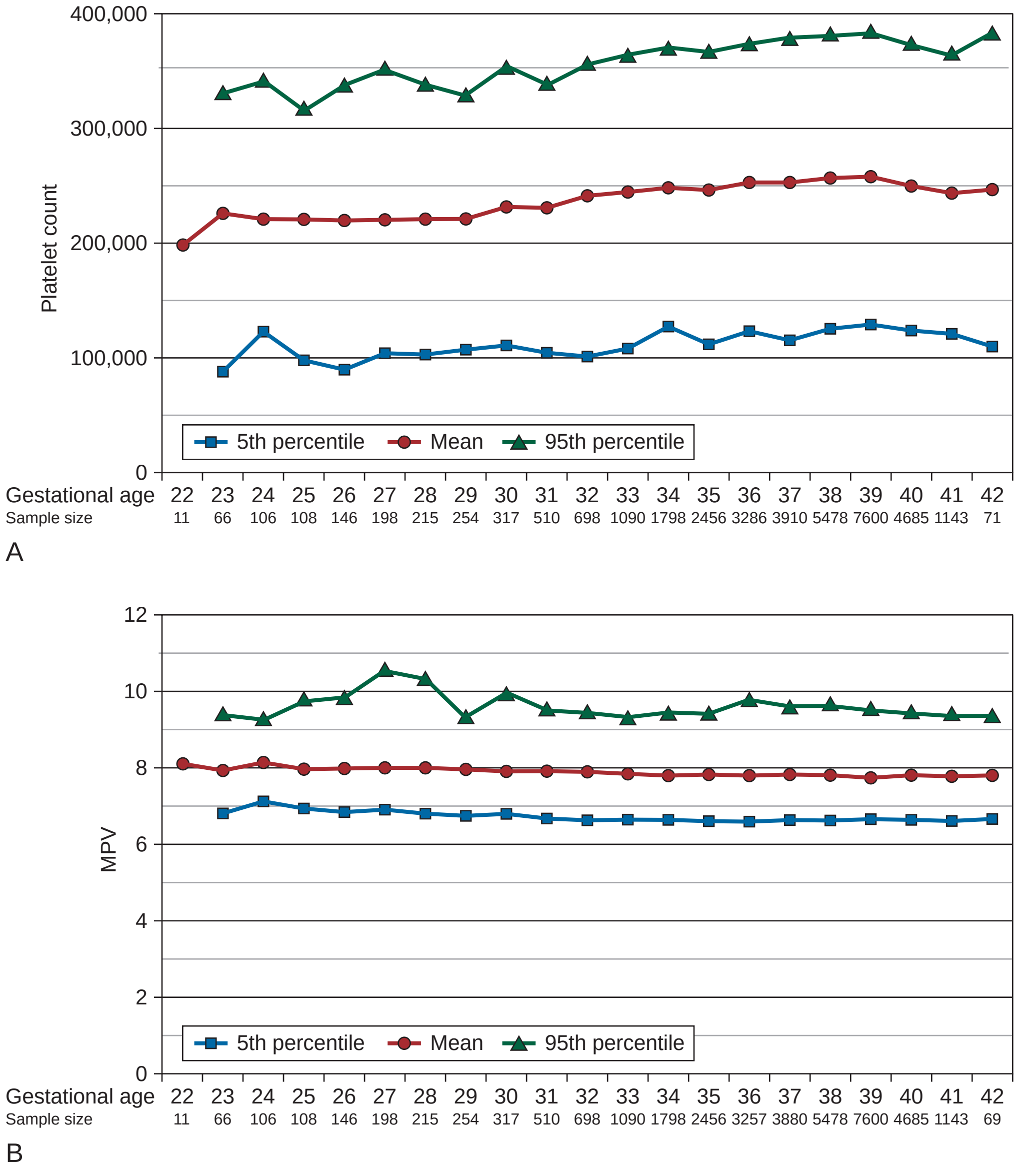
From Rosse C, Kraemer MJ, Dillon TL, et al: Bone marrow cell populations of normal infants; the predominance of lymphocytes. J Lab Clin Med *89:1228, 1997.*

*Percentages of cell types (mean ± standard deviation) is tibial bone marrow of infants from birth to 18 months of age. Data were obtained from normal American infants of black, white, and Asian racial origin. The changes in the marrow during the first 18 months of postnatal life are based on different counts of 1000 cells classified on stained smears on each of 10 serial marrow samples aspirated from the same population of infants. Criteria for including bone marrow data in this study consisted of absence of any clinical evidence of disease, normal rate of growth, and normal serum protein and transerffin saturations.

[†] N = number of infants studied at each stage.

[‡] Expressed in round figures for facilitating comparison. Means ± standard deviation were calculated from values obtained in individual infants, and statistical comparisons were performed.



Appendix 46 The first recorded platelet counts (**A**) and MPV determinations (**B**) obtained in the first three days after birth, are shown for neonates of 22 to 42 weeks gestation. Mean values are given by the red line and the 5th and 95th percentiles are given by the green and blue lines. **A,** Initial platelet counts. (b) Initial MPV measurement. Platelet values were measured using automated Beckman Coulter Hematology Analyzers (Beckman Coulter Inc., Fla., USA). *(From Wiedmeier SE, Henry E, Sola-Visner MC, et al: Platelet reference ranges for neonates, defined using data from over 47 000 patients in a multihospital healthcare system.* J Perinatol *29:130–136, 2009.)*

APPENDIX 47 Circulating Platelet Counts and Serum TPO Levels at Different Ages[*]

Age Categories	**Platelet Count (10^9/L)**	**Serum TPO (fmol/L)**
Core blood	288 ± 53	3.73 ± 1.48 (1.44-6.74)
2 days	303 ± 48	5.92 ± 1.4 (4.33-9.18)
5 days	338 ± 59	4.32 ± 0.94 (2.38-5.76)
1 month	343 ± 72	3.77 ± 1.45 (2.25-7.60)
2-11 months	365 ± 49	2.10 ± 0.69 (1.04-4.24)
1-2 years	314 ± 78	2.23 ± 0.89 (0.43-4.54)
3-4 years	304 ± 66	1.97 ± 0.67 (0.98-3.73)
5-6 years	303 ± 65	1.67 ± 0.66 (0.58-3.14)
7-10 years	295 ± 58	1.39 ± 0.63 (0.53-2.94)
11-15 years	251 ± 40	1.24 ± 0.40 (0.49-1.99)
Adult	234 ± 48	0.83 ± 0.36 (0.25-1.72)

From Ishiguro A, Nakahata T, Matsubara K, et al: Age-related changes in thrombopoietin in children: reference interval for serum thrombopoietin levels. Br J Haematol *106(4):884–888, 1999.*

TPO, Thrombopoietin.

[*] All values for children are significantly different (*P* <.001, Mann-Whitney U test) from values for adults. Data are expressed as mean ± standard deviation. The range of values for TPO is reported in parentheses.

APPENDIX 48 Comparison of Selected Coagulation Factor Values in Newborns[*]

Age	**Fibrinogen (mg/dL)**	**F II (U/mL)**	**F VIII (U/mL)**	**F IX (U/mL)**	**F XII (U/mL)**	**Antithrombin (U/mL)**	**Protein C (U/mL)**

From Andrew M, Vegh P, Johnston M, et al: Maturation of the hemostatic system during childhood. Blood *80:1998, 1992.*

y, Years.

[*] All values are expressed in units per milliliter, where for all factors pooled plasma contains 1.0 U/mL, with the exception of free protein S, which contains a mean of 0.4 U/mL. All values are given as a mean, followed by the lower and upper boundary encompassing 95% of the population. Between 20 and 30 samples were assayed for each value for each age group. Some measurements were skewed because of a disproportionate number of high values. The lower limits, which exclude the lower 2.5% of the population, are given.

[†] Values that are significantly different from those of adults.

Klarmann D, Eggert C, Geisen C, et al: Association of ABO(H) and I blood group system development with von Willebrand factor and Factor VIII plasma levels in children and adolescents. Transfusion *50:1571–1580, 2010.*

[*] For each assay the first two rows show the median and the central 90% reference intervals. The second two rows show the number *(N)* of individual samples and the ratio of males *(M)* to females *(F)* for each group.

[†] Blood group A/b/AB values are significantly different from blood group O values (*P* <.01 Mann-Whitney test).

APPENDIX 58 Reference Values for the Fibrinolytic System in Healthy Children Aged 1 to 16 Years Compared with Adults

	AGE			
	1 to 5 y	**6 to 10 y**	**11 to 16 y**	**Adult**
	Mean (Boundary)	***Mean (Boundary)***	***Mean (Boundary)***	***Mean (Boundary)***
Plasminogen (U/mL)	0.98 (0.78-1.18)	0.92 (0.75-1.08)	0.86 (0.68-1.03)	0.99 (0.77-1.22)
Tissue plasminogen activator (TPA) (ng/mL)	2.15 (1-4.5)*	2.42 (1.0-5)*	2.16 (1-4)*	4.90 (1.4-8.4)
α_2-antiplasm (α-AP) (U/mL)	1.05 (0.93-1.17)	0.99 (0.89-1.10)	0.98 (0.78-1.18)	1.02 (0.68-1.36)
Plasminogen activator inhibitor (PAI) (U/mL)	5.42 (1-10)	6.79 (2-12)*	6.07 (2-10)	3.60 (0-11)

From Andrew M, Vegh P, Johnston M, et al: Maturation of the hemostatic system during childhood. Blood *89:1998, 1992.*

For α2-AP, values are expressed as units per millimeter, where pooled plasma contains 1 U/mL. Values for TPA are given as nanograms per millimeter. Values for PAI are given as U/mL, where 1 U of PAI activity is defined as the amount of PAI that inhibits 1 IU of human-single chain TPA. All values are given as the mean, followed by the lower and upper boundary encompassing 95% of the population (boundary).

*Values that are significantly different from those of adults.

APPENDIX 59 Endogenous Plasma Concentrations of Thrombin-Antithrombin Complexes (TATs) and Prothrombin Fragment 1.2 (F1.2) in Children and Adults*

	1-5 Years	**6-10 Years**	**11-16 Years**	**20-45 Years**
TAT (μg/L)	2.3 ± 0.08	2.38 ± 0.13	2.8 ± 0.18	2.15 ± 0.09
F1.2 (nm/L)	1.04 ± 0.06	0.87 ± 0.07	0.82 ± 0.06	0.83 ± 0.06

From Andrew M, Mitchell L, Vegh P, et al: Thrombin regulation in children differs from adults in the absence and presence of heparin. Thromb Haemost *72:836, 1994.*

*Data are expressed as mean ± standard error of the mean.

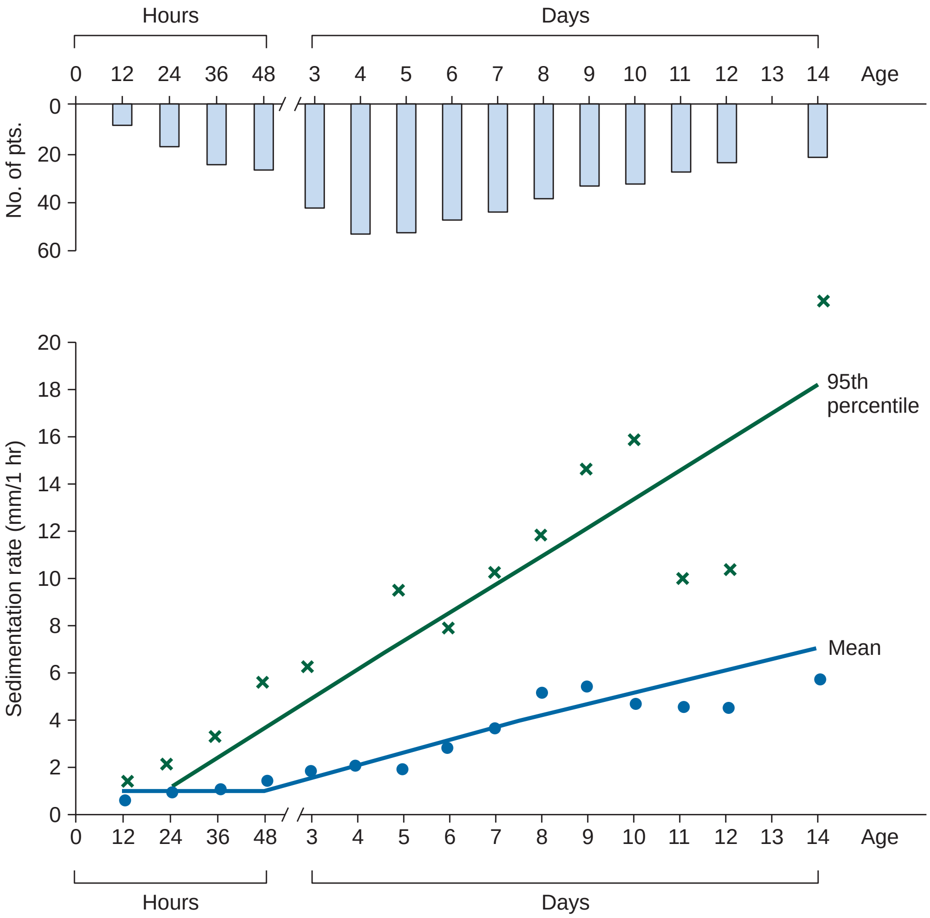
From Colantonio DA, Kyriakopoulou, Chan MK, et al: Closing the Gaps in Pediatric Laboratory Reference Intervals: A CALIPER Database of 40 Biochemical Markers in a Healthy and Multiethnic Population of Children. Clin Chem *58:854–868, 2012.*

Albumin G, Albumin assay with bromcresol green; *Albumin P*, albumin assay with bromcresol purple.

*Bold and underlined values indicate sex-specific differences within age partitions.



Appendix 75 Sedimentation rate in the newborn period. The erythrocyte sedimentation rate was measured in capillary blood in healthy full-term and low-birth-weight newborns. Normal values ranged from 1 mm/h at 12 hours of age to 17mm/h at 14 days of age. All values of neonates with hematocrit values less than 40% were corrected to 40%. *(From Adler SM, Denton RL: The erythrocyte sedimentation rate in the newborn period.* J Pediatr *86:942, 1975.)*

Glucose phosphate isomerase (GPI) deficiency *(Continued)*
  inheritance, 586-588
  mutations, 587t
  therapy, 588
Glucose transporter 1 (Glut1), 479
  defect, 570
  model, 570f
  molecules, impact, 491
Glucose transporter, adducin (attachment), 491
Glutamate formiminotransferase deficiency, 337
Glutathione cycle, 610f
Glutathione metabolism, disorders, 65, 843-845, 844t
Glutathione S-transferase (GST) B, bilirubin (binding), 104-105
Glycogen synthase kinase 3β (GSK-3β), 36-37
Glycolipid antigens, alteration, 1453
Glycolipids, 456-458
Glycolytic enzymes (binding), N-terminal sequence (usage), 467-469
Glycolytic metabolon, 470f
Glycophorin A (GPA), 473-474
  defects, 475-476
  organization, 474f-475f
Glycophorin B (GPB), 474
  defects, 475-476
  organization, 475f
Glycophorin C (GPC), 474-475
  defects, 557
  interactions, 487-488
  variations, 476
Glycophorin D (GPD), 474-475
  interactions, 487-488
  variations, 476
Glycophorin E (GPE), 475
  defects, 475-476
  organization, 475f
Glycophorins, 473-476
  malarial invasion receptors, 476
  mutations, 475-476
  variants, 475f
Glycoprotein (GP)
  antigens, alteration, 1453
  IIb/IIIa complex, thrombin (impact), 132f
  Kell glycoprotein, 477
  Kidd glycoprotein, 477
  Lutheran glycoprotein molecule, 477-478
  LW glycoprotein, 478
Glycoprotein Ib/IX (GPIb/IX) complex
  biology, 1015-1016
  defect (Bernard-Soulier syndrome), 1015-1017
Glycoprotein Ib/IX (GPIb/IX) receptor, structure, 1016f
Glycosaminoglycan (GAG), 937
Glycosphingolipis, 457f
Glycosylphosphatididylinositol (GPI), 165
Glycosyl phosphatidylinositol-anchored proteins (GPI-APs), 432f
  deficiency, 437-440
  expression, 433f
  PNH deficiency, 433b
  synthesis, genes (congenital abnormalities), 437
GM_1 gangliosidosis, 935-936
GM_2 gangliosidosis, 936-937
Gonadal cancers, annual aged-adjusted incidence rates, 2067t-2068t
Gonadal function (germ cell tumors), 2097-2098
Gonadal germ cell tumors, 1520-1521
Gonadoblastoma, 2066, 2069
  mixed germ cell-stromal tumors, 2066f
Gonadogenesis, 2058-2059
Good syndrome, 911
Gorlin syndrome, 1787-1788
Gout, 540
gp130, 15
GPIb/IX complex, thrombin (impact), 132f
G-protein-coupled receptor (GPCR) family, 16
G protein-coupled receptors, 1019-1020
Grade II fibrillary astrocytoma, 1817f
Gradient-driven passive transporters, 508f
Graft rejection, 266
Graft-*versus*-host disease (GVHD), 266-287
  effect, 1461-1462
  pain, relationship, 2368
Graft-*versus*-leukemia (GVL)
  response, generation, 1453
Granule defects, 1022-1023
  alpha-granule defects, 1022
  dense granule defects, 1021-1022
  platelet storage granule defects, 1021
Granulocyte colony-stimulating factor (G-CSF), 15-17
  administration, response, 805f
  dose-limiting toxicity, absence, 49
  factors, 2264
  usage, controversy, 247
Granulocyte colony stimulating factor (G-CSF), HSC activation, 9
Granulocyte-macrophage colony-stimulating factor (GM-CSF), 15, 17-18
  complex ligands, 23
  factors, 2264
  mutations, 1561f
  response, myelosuppression (impact), 43
Granulocyte monocyte progenitors (GMPs), 9
Granulocytes, 774-780
  chemoattractants, 784t
  colony-forming cells, 11
  function, disorders, 819-846
  intrinsic defects, 801-807
  quantitative granulocyte disorders, 800-819
Granulocytic sarcomas, 2228
Granulocytic transfusions, 1149
Granulocytopenia, 1180-1181
Granulosa cell tumor, menses (onset), 2214f
Gray matter, 1791
GROUCHO domain factors, 35
Group A haplotypes, presence, 1464f
Group B haplotypes, gene content, 1464f
Group B retinoblastoma, vincristine/carboplatin courses (response), 1769f
Group E retinoblastoma, dilated eye examination, 1755f
Growing teratoma syndrome, 2091
Growth factors
  erythropoiesis, relationship, 38-39
  myelopoiesis, relationship, 40-41
  pathways, importance, 36
  signaling, 1533
  stem cells, relationship, 36-37
Growth hormone (GH) deficiency, 2415
Growth pathways (modulation), fusion oncoproteins (usage), 1900-1901
Gruppo Italiano Trapianti di Midolio Osseo (GITMO), 174
GTPase-activating protein (GAP), 1560-1562
Guanine-nucleotide-releasing factor (GRF), 31-32
Guanosine triphosphate (GTP), 31-32
Guillain-Barré syndrome (GBS), 1161

H
HABA binding, 121
Haemophilus influenzae Type B vaccine, 546
Hageman factor (factor XII), 978
  deficiencies, 1060
Hairy and Enhancer of Split 1 (HES-1), 36
Hamartomas, 1872-1874
  hypothalamic hamartomas, 1873f
  imaging/histology, 1873
  management, 1874
  prognosis, 1874
Hande-Garrow definitions, 2284b
Hand-foot syndrome, 686f
H antigen, 1129-1130
Haplotypes
  analysis, 733-735
  chromosomal haplotypes, linkage, 734f
Hapten formation, 1091
Haptocorrin (transcobalamin I) deficiency, 338-339
Haptoglobin levels, reference ranges, 2527t
HAX1, mutations, 46
Hb H disease, 66
HDAC inhibitors, 1711-1712
Head, sagittal-CT reconstructed image, 2244f
Health care proxy, 2325
Hearing, childhood cancer (relationship), 2419-2420
Heart disease, hematologic manifestations, 1184
Hedgehog signaling, 1327f
Heinz bodies, 11
  hemolytic anemias, 536
Helper T-cell differentiation/function, 878-881
Hemangioblastomas, 1823-1824, 2164
  clinical presentation, 1823
  imaging/histology, 1823
  management, 1823
  prognosis, 1823-1824
  T2-weighted fluid-attenuated FLAIR/post-gadolinium enhanced images, 2165f
Hemangiomas, evidence, 1098b
Hemangiopericytoma, 1957-1958
Hematemesis, 61
Hematocrit
  levels, 55-56
  reference ranges, 2490t, 2505f
  sex-stratified/age-stratified pediatric reference ranges, 296f
Hematologic abnormalities
  Diamond-Blackfan anemia, 230-231
  dyskeratosis congenita, 223
  Fanconi anemia, 190
Hematologic disease
  distribution/expression, geographic variability, 1220-1222
  G6PD deficiency, coexistence, 626-627
  management, 203-204, 221-222
Hematologic disorders (uniqueness), 1222
Hematologic maintenance, relapse (site), 2236
Hematologic malignancies, 1484

  atypical hemolytic-uremic syndrome, 1096-1097
  enteropathic hemolytic-uremic syndrome, 1095-1096
Hemophagocytic lymphohistiocytosis (HL) (HLH), 285, 2112-2120
  clinical features, 2113-2114
    incidence, 2114f
  comparison, 2120t
  diagnostic guidelines, 2112b
  familial HL (FHL), 2114-2116
    genes, 2115t
  genetic syndromes, 2116
  hematopoietic cell transplantation, 2119-2120
  histopathologic findings, 2116f
  HLH-associated gene mutations, cytotoxic function (mechanics), 2113f
  incidence, 2112-2113
  infection-associated HLH, 2116-2117
  initial therapy, 2118
  laboratory findings, abnormality, 2114f
  malignancy-associated HLH, 2117
  management, 2117-2120
  secondary HLH, 2116-2117
    management, 2118-2119
  supportive care, 2119
Hemophilia
  clinical manifestations, 1029-1030
  comprehensive care/home therapy, 1039
  demographics/classification, 1029
  genetic testing, 1034
  hemorrhages, treatment, 1031t
  laboratory evaluation, 1033-1034
  musculoskeletal bleeding, 1030
  partial thromboplastin time (PTT), 1033
  pathophysiology, 1029
  surgery, preparation, 1031-1032
  symptomatic carriers, 1033
  treatment, fundamentals, 1034-1039
Hemophilia A, 1028-1039
  dose, calculation, 1034-1035
  factor VIII treatment products, 1035-1036
  gene therapy, 1039
  laboratory evaluation, 1033-1034
  prophylactic factor VIII therapy, 1035
  transfusion therapy, complications, 1039
  treatment, 1034-1036
    inhibitory antibodies, presence, 1036-1038
Hemophilia B, 1028-1039
  dose, calculation, 1038
  factor (factor IX), 972
  gene therapy, 1039
  laboratory evaluation, 1033-1034
  transfusion therapy, complications, 1039
  treatment, factor IX inhibitors (usage), 1039
Hemorrhage, 1032
  abdominal hemorrhage, 60-61
  acquired hemorrhagic disorders, 1103-1110
  adrenal hemorrhage, 61
  causes, 61
  cranial hemorrhage, 60
  erythrocyte loss, excess, 58b
  fetal hemorrhage, clinical manifestations, 61-62
  fetus/newborn, 57-62
  hepatic hemorrhage, 61
  intracranial hemorrhage, 60
  intrapartum hemorrhage, 60-61
Hemorrhage *(Continued)*
  life-threatening hemorrhages, 1030-1031
    management, 1086-1087
  neonatal hemorrhage, clinical manifestations, 61-62
  postpartum hemorrhage, 61
  prenatal hemorrhage, 57-60
  splenic hemorrhage, 61
  subgaleal hemorrhage, 60
  traumatic fetal hemorrhage, 59
  treatment, 1031t
Hemorrhagic disease of the newborn (HDN), 137-138
  historical background, 137
  newborn (bleeding), vitamin K deficiency (impact), 137-138
  prophylactic vitamin K (VK) administration, 137
Hemorrhagic pituitary adenoma, T1-weighted images, 1872f
Hemostasis
  developmental hemostasis, clinical aspects, 133-148
  fetal hemostasis, 133
  hereditary coagulation factor deficiencies, 134-137
  platelet granules, role, 956-957
  system, development, 129f
Hemostatic challenges, clinical history, 1001
Hemostatic failure, systemic disease manifestation (tropics), 1219-1220
Hemostatic system, catalysts
  regulation points, 966f
  schematic, 965f
  termination, 967-968
Henoch-Schönlein purpura (HSP), 1101
Heparin
  cofactor II (Leuserpin 2), 980
  therapy, 146-147
  usage, 146
Heparin-induced thrombocytopenia/thrombosis (HIT), 1091-1092
  diagnosis, 1092
  pathogenesis, 1091-1092
  treatment, 1092
Hepatic adenoma (gastrointestinal tumors), 2187-2189
Hepatic BSP clearance tests, 124
Hepatic failure, 2357
Hepatic hemorrhage, 61
Hepatic Kupffer cells, 39-40
Hepatic mesenchymomas (embryonal sarcomas), 2186
Hepatic metabolism, pharmacokinetics (relationship), 1417-1418
Hepatitis B virus (HBV), 1142
Hepatitis C virus (HCV), 1142
Hepatitis, impact, 164
Hepatobiliary intervention, percutaneous transhepatic cholangiogram, 2248f
Hepatobiliary system, chronic organ damage (SCA), 698
Hepatoblastoma, 1502-1504
  abdominal mass, presence, 2182f
  acquired genetic changes, 1895-1896
  age distribution, 1887f
  chemotherapy, usage, 1897-1900
  cooperative group studies (Europe/North America), 1898t
  embryonal epithelial hepatoblastoma, 1896f
  environmental exposures, 1891
  epidemiology, 1886-1887
  exophytic liver mass, CT/MRI images, 2184f
Hepatoblastoma *(Continued)*
  fetal epithelial hepatoblastoma, 1896f
  genetic predisposition, 1887-1891
  high-stage hepatoblastoma, CT scan, 1894f
  IVC, direct extension (coronal contrast-enhanced CT), 2177f
  metastatic hepatoblastoma, AFP levels (increase), 2185f
  molecular aberrations, 1896-1897
  North American postsurgical staging, European presurgical staging (contrast), 1893t
  origins, 1887
  overgrowth syndromes, relationship, 1889
  pathology, 1894-1895
  pediatric liver tumors, immunohistochemical evaluation, 1895t
  pediatric tumors, International Consensus Classification, 1894t
  prematurity, risk factor, 1891
  pretreatment imaging-defined staging protocol presurgical staging system, usage, 1893f
  pulmonary metastases, 1521
  recurrent/refractory disease, treatment, 1899-1900
  resected hepatoblastoma tumor, gross pathology, 1895f
  staging, 1892-1894
  superiority, presence (MRI), 2183f
  syndromes, 1890
  treatment, chemotherapy (usage), 1897-1900
  tumor, genome-wide copy number comparative genomic hybridization (CGH) scan, 1899f
Hepatocellular carcinoma (HCC)
  differentiation, 1897f
  fibrolamellar hepatocellular carcinoma, 1897f
  gastrointestinal tumors, 2184-2186
  genetic syndromes, 1890
  heterogeneous mass, T2-weighted/DWI images, 2186f
  pathology, 1894-1895
  treatment, 1900
Hepatocellular damage, syndrome, 94
Hepatosplenic fungal infection, MRI, 2237f
Hepatosplenic T-cell lymphoma, 1382
Hepatosplenomegaly, development, 443f
Hereditary angioedema (C1 inhibitor deficiency), 919
Hereditary blood disorders, 1221
Hereditary coagulation factor deficiencies, 134-137
  clinical findings, 135
  delivery, mode, 135
  diagnosis, 135
  inheritance, 134-135
  treatment, 135
Hereditary coproporphyria, 400-402
Hereditary cryohydrocytosis, 568-570
  type 1, 568-569
  type 2, 570
Hereditary elliptocytosis (HE), 65, 548-559
  alpha-spectrin^{LELY}, combination, 551
  alpha-spectrin, mutations, triple-helical model, 554f
  beta-spectrin mutations, triple-helical model, 554f
  chronic hemolysis/hereditary pyropoikilocytosis, combination, 551-552

Hereditary elliptocytosis (HE) *(Continued)*
  clinical subtypes, 550t
  clinical syndromes, 549-552
  common/mild hereditary elliptocytosis, 549
  dyserythropoiesis, combination, 551
  ektacytometry, 553
  eosin-5′-maleimide-binding test, 553
  examples, 521f, 523f-524f
  genetic analyses, 553
  genetics, 549
  glycophorin C defects, 557
  hereditary pyropoikilocytosis, relationship, 557-558, 558f
  hereditary spherocytosis, relationship, 558f
  heterozygous hereditary elliptocytosis, 549-551
  history, 548-549
  infantile poikilocytosis, combination, 550-551
  laboratory methods, 553
  malaria, relationship, 558-559
  pathophysiology, 553-558
  peripheral blood smears, 548f
  prevalence, 549
  protein 4.1R
    defects, 556-557
    deficiency, 556f
    mutations, 557f
  red cells, thermal sensitivity, 553
  silent carrier state, 549
  Southeast Asian ovalocytosis, 552
    subtype, 570-571
  spectrin
    defects, 553-556
    oligomerization, abnormality, 553
    thermal sensitivity, 553
    tryptic maps, 553
  spherocytic hereditary elliptocytosis, 552
    relationship, 557-558
  sporadic hemolysis, combination, 549-550
  treatment, 552-553
Hereditary folate malabsorption, 336
Hereditary hemochromatosis, 365-367
Hereditary hemorrhagic telangiectasia, 1196
Hereditary orotic aciduria, 341-342
Hereditary paraganglioma (hereditary PGL), 1285-1286
  genetics, 1285-1286
  incidence, 1285
  tumor risks/surveillance, 1286
Hereditary persistence (fetal hemoglobin), 740-742
  deletion mutations, 740
Hereditary pulmonary fibrosis, 219
Hereditary pyropoikilocytosis (HPP), 65, 548-559
  hereditary elliptocytosis
    combination, 551-552
    relationship, 557-558
Hereditary retinoblastoma (RB), 1278-1282
  genetics, 1281
  incidence, 1278-1280
  soft tissue sarcoma, risk/type, 1774t
  survivors, risk/cancers, 1773t
  tumor risks/surveillance, 1281-1282
Hereditary spherocytosis (HSO) (HS), 53-54, 515-548
  acidified glycerol lysis test, 534-535
  adducin, impact, 548
  alpha-spectrin mutations, impact, 523t
  angioid streaks, 540
Hereditary spherocytosis (HSO) (HS) *(Continued)*
  animal/fish models, 546-548
  ankyrin
    defects, 525-526
    mutants, 547
    mutations, impact, 525t
  antibiotic prophylaxis, 546
  aplastic crises, 536, 538-540
  autohemolysis test, 534-535
  babesiosis, 541-542
  band 3
    defect, 569-570
    mutants, 547
  band 3 mutations
    impact, 526t
    presence, 527f
  beta-spectrin mutations
    impact, 524t
    presence, 524f
  beta-thalassemic trait, 537
  camouflage, 537
  cause, protein 4.2 deficiency (impact), 498
  cellular deformability, loss, 529-530
  clinical features, 523
  clinical/laboratory classification, 518t
  clinical presentation, 517-521
  compensated hemolysis, explanation process, 519
  complications, 537-540
  congenital dyserythropoietic anemia, type II, 536-537
  corticosteroid therapy, 545
  crises, 538-540
  deficiencies, impact, 521f
  dematin, impact, 548
  differential diagnosis, 536-537
  distal renal tubular acidosis (dRTA), 527
  dominant HS, beta-spectrin defects, 523-525
  erythrocytes, osmotic gradient ektacytometry, 536f
  erythrostasis, 531-532
  example, 517-519
  extramedullary hematopoiesis, 540
  folic acid, impact, 546
  fragility test, 534-535
  gallstones, 537-538
    proportion, 538f
  genetics, 516
  gout, 540
  Haemophilus influenzae Type B vaccine, 546
  Heinz body hemolytic anemias, 536
  hemochromatosis, 540
  hemoglobin SC, 537
  hemolytic crises, 538
  hereditary elliptocytosis (HE), relationship, 558f
  history, 516
  hypertonic cryohemolysis test, 535
  immunohemolytic anemias, 536
  impact, 492
  iron deficiency, 537
  laboratory characteristics, 533-536
  leg ulcers, 540
  low-temperature cation leak, 569-570
  malaria, 541-542
  mechanical stability, 522f
  megaloblastic crises, 540
Hereditary spherocytosis (HSO) (HS) *(Continued)*
  membrane
    defects, 521f
    surface loss, vesiculation (impact), 528-529
  membrane protein
    defects, etiology, 521-528
    deficiency, patterns (impact), 522
    measurements, 535-536
  meningococcal vaccines, 546
  mild HS, 519
  moderate HS, 520
  neonates
    ABO incompatibility, 536
    relationship, 520-521
  nonerythroid manifestations, 540
  obstructive liver disease, 537
  osmotic fragility, 531f
    test, 534
  osmotic gradient ektacytometry, 535
  pathophysiology, 528-533, 530f
  peripheral blood morphologic findings, 562f
  peripheral blood smear, 517f
  pink test, 534-535
  pneumococcal vaccines, 545-546
  pregnancy, relationship, 520
  prevalence, 516
  protein 4.1$, 547-548
  protein 4.2, 547
    mutations, impact, 528t
  recessive HS
    alpha-spectrin defects, 522-523
    protein 4.2 defects, 527-528
    protein 4.2 mutations, association, 528f
  red cells
    dehydration, benefits, 532-533
    indices, 533-534
    morphologic findings, 524f
    morphology, 533
  RNA/DNA measurements, 535-536
  scleral icterus, presence, 519f
  severe HS, 520
    homozygous alpha-spectrin defect, impact, 524f
  silent carrier state, 519
  spectrin mutants, 546-547
  splenectomy, 541-545
    adverse vascular events, risk, 542t
    partial splenectomy, long-term follow-up, 545f
  splenic rupture, 540
  splenic sequestration/conditioning, 530-531
  splenic trapping, consequences, 532
  surface, comparison, 529f
  therapies, 545-546
  thrombosis/thromboembolic diseases, 542-543
  vaccination, 545-546
Hereditary stomatocytosis (HSt), 537
  disorders, temperature function, 571f
  mild hereditary stomatocytosis, 568
  pathophysiology, 562-564
  syndromes, 65, 568-571
    features, 561t
Hereditary thrombophilia, patient evaluation, 1074
Hereditary thrombotic disorders, 1062-1069

Hereditary xerocytosis (HX), 565-568
  clinical features, 565-566
  disorders, temperature function, 571f
  iron overload, 566
  nonimmune hydrops, 566
  osmotic gradient ektacytometry, 563f
  pathophysiology, 566-567
  peripheral blood morphologic findings, 562f
  piezo1 mechanotransducer channel, defect, 566-567
  syndromes, features, 561t
  treatment, 567
Heritability, 188b
Herpes simplex encephalitis, 908
Heterogeneous cells, properties/assays (schematic view), 8f
Heterotropic effectors, impact, 646, 646f
Heterozygotes, G6PD deficiency, 624
Heterozygous antithrombin deficiency, assay measurements, 1063t
Heterozygous beta-thalassemia, peripheral blood smears, 750f
Heterozygous carriers, malignant disease (risk), 201
Heterozygous hereditary elliptocytosis, 549-551
Heterozygous protein C deficiency, assay measurement, 1065t
Heterozygous protein S deficiency, assay measurements, 1066t
Heterozygous prothrombotic disorders, 145
  treatment, 145
Hexokinase (HK) activity, 583f
Hexokinase (HK) deficiency, 582-585
  biochemistry, 582-584
  clinical manifestations, 582
  genetics, 584-585
  therapy, 585
Hexokinase (HK) variants, hemolytic anemia (association), 583f
Hexose monophosphate shunt/pathways, disorders, 64-65
High-A_2 beta-thalassemia, 750-751
High-A_2 high-F beta-thalassemia, 751
High-dose chemotherapy, stem cell rescue (combination), 1805-1806
High-grade angiosarcoma, composition, 1969f
High-grade astrocytomas (HGAs), 1824-1827
  clinical presentation, 1825
  imaging/histology, 1825-1826
  management, 1826-1827
  prognosis, 1827
  supratentorial HGAs, 1824-1827
High-grade osteosarcoma, 2027f
High-grade undifferentiated sarcoma, 1981f
High-income countries, ALL (event-free survival), 2480f
High-intensity focused ultrasound, 2246
High-molecular-weight Kininogen (HMWK) (Fitzgerald factor) (Williams factor), 978-979
High-oxygen affinity hemoglobin variants, 654, 666-667
High-performance liquid chromatography (HPLC), 107-109
High phosphatidylcholine hemolytic anemia, 565-568
High pressure liquid chromatographic (HPLC) analysis, 117
High proliferative potential colony-forming cell (HPP-CFC) assay, 8
High-responding factor VIII inhibitors, 1037-1038
High-risk neuroblastoma
  chimeric antiGD2 antibody/immunocytokine, efficacy, 1705f
  event-free survival, improvement, 1703f
  tandem transplant, 1704f
High sensitivity C-reactive protein, age-specific/sex-specific pediatric reference intervals, 2526t
Hips
  joints, magnetic resonance imaging, 1515f
  sclerotic osteoid osteoma, axial CT, 2244f
Hirschsprung's disease, 118
Histiocyte popcorn neoplastic cells, presence, 1378f
Histocompatibility antigens, 1453
Histologic grading system (Children's Oncology Group), 1953t
Histologic subtype levels, 2077t
Histone deacetylase (HDAC) inhibitors, 1320
  usage, 1589
Historical French-American-British (FAB) subtypes, 1382f
Hodgkin cells, mononuclear variants, 1629f
Hodgkin disease (HD), 280, 1484-1485
  chest computed tomography scan, 2269f
  chest radiograph, 2269f
Hodgkin lymphoma, 280, 1377-1379, 1629-1648, 2228-2233
  age-specific/gender-specific incidence rates, 1632f
  Ann Arbor staging classification, 1635t
  breast cancer, cumulative incidence, 2405f
  chest/abdomen/pelvis, contrast-enhanced CT images, 2233f
  chest x-ray, 1635f
  children/adolescents
    therapy, favorable response, 1643t
    treatment, late effects, 1647t
  classic Hodgkin lymphoma, 1379, 1629-1645
  CT/FDG-PET, 2172f
  FDG response (determination), Five-Point Deauville criteria (usage), 2233t
  high-risk patients, combined-modality treatment strategy/results (multicenter trials), 1642t
  intermediate-risk patients, combined-modality treatment strategy/results (multicenter trials), 1642t
  investigations, children/adolescents, 1634t
  low-risk patients, combined-modality treatment strategy/results (multicenter trials), 1641t
  mediastinal/bilateral hilar nodal disease, 2232f
  mediastinal mass/left pleural effusion, contrast enhanced CT, 2231f
  MR angiogram/unenhanced head CT, 2232f
  nodal regions, Ann Arbor staging classification, 1636f
  nodular lymphocyte-predominance Hodgkin lymphoma, lymphocyte/histiocyte popcorn neoplastic cells (presence), 1378f
  nonspecific upper respiratory infection (chest x-ray), 2230f
  pediatric Hodgkin lymphoma, clinical trials (risk group definitions), 1637t
  relapse, treatment, 1645-1646
  staging, 2228-2233
Hodgkin lymphoma *(Continued)*
  therapy, late effects, 1646-1648
  treatment
    radiation fields, 1644f

  abnormalities (anemia of inflammation), 370
  absorption, 346-348
  acquisition, 346-351
  acute poisoning, 369-370
  balance, extremes, 355-370
  bioavailability, problem, 356-357
  chelation therapeutics, 761-763
  chelators
    chemical structures, 761f
    orally active iron chelators, 762-763
  deposition, severe beta-thalassemia, 757
  dietary sources, 356
  distribution, 346-351
  duodenal transfer, 347f
  economy, 346f
  effects (fetus), 365
  hereditary hemochromatosis, 365-367
  insertion, 402-406
  intake, inadequacy, 356-358
  intercellular transport, 348-349
  intracellular metabolism, 349-351
  iron-dependent BMP signaling, 358f
  iron-protein complexes, 344-345
  malabsorption, 357-358
  maternal stores, 365
  metabolism, protein regulation, 352-355
  neonatal hemochromatosis (NH), 368
  oral supplementation, response problems (causes), 364b
  overload, 566
  oxidation, 344
  parenteral replacement, 363-364
  physiologic chemistry, 344-346
  replacement (infants), 364-365
  role, 351-352
  saturation, 2502t-2503t
  status
    assessment, clinical laboratory tests (usage), 362t
    indicators, 2502t
  systemic loss, 358-359
  toxicity, 345-346
  utilization, disorders, 370
  vitamin supplementation, 763-764
Iron deficiency, 355-365, 537
  anemia, 360-361
    causes, 357b
  consequences, 359-361
  development, phases, 356
  diagnosis, 361-363
  epidemiology, 355-356
  epithelial changes, 360
  etiology, 356-359
  hematologic patterns, 751t
  histograms, 302f
  neurocognitive effects, 359-360
  oral supplementation, usage, 363
  peripheral blood smear, 360f
  pica, 360
Iron deficiency *(Continued)*
  screening tests, sensitivity/specificity/cost, 363t
  thalassemia trait, differentiation (formulas), 752t
  treatment, 363-365
Iron-dependent bone morphogenetic protein (BMP) signaling, 358f
Iron overload, 365-370
  advantage, 365
  African iron overload syndrome, 367-368
  consequences, 368-369
  erythroid hyperplasia/erythropoiesis ineffectiveness, impact, 368
  infectious agents, impact, 370b
  measurement, 760-761
  opportunistic infections, impact, 369
  rate/extent, 760
  risk, child workup algorithm, 366f
  thalassemia intermedia, 763
  therapy, 760-761
Iron regulatory protein (IRP) regulation, 353f
Iron response element (IRE) regulation, 353f
Irradiation-associated second cancers, childhood cancer survivors (evaluation), 2406t
Irreversible electroporation (IRE), 2246
Isoimmunization, 111-112
Isolated cytopenias, inherited bone marrow failure syndromes (association), 229-251
Isolated hemihyperplasia (IHH), 1288-1289
  genetics, 1288
  incidence, 1288
  tumor risks/surveillance, 1288-1289
ITCH deficiency, 906

J
Jacobsen syndrome, 142-143
Jagged (stem cell factor), 18-19
JAK2 aggregation, 29-31
JAK2V617F mutation, 29-31
JAK3 deficiency, 892
JAK activation, 28-29
JAK, heterodimeric receptors (association), 31
JAK mutations (pediatric leukemia), 1322-1323
JAK proteins, activation, 31
JAK/STAT (activation), HGFR (usage), 30t
JAK-STAT pathway, 15
Jaundice, 107
  breastfeeding, relationship, 110-111
  cause, 119
  disease consideration, 110
  glucose-6-phosphate dehydrogenase (G6PD), association, 620t
  hyponatremia, association, 112
  neonatal jaundice (NNJ), 64, 620-621
  physiologic jaundice, 110
Joint bleeding, long-term complications, 1032-1033
Juvenile follicular lymphoma, 1668
Juvenile idiopathic arthritis (rheumatoid arthritis), 1169
Juvenile myelomonocytic leukemia (JMML), 32, 276, 1396-1397, 1602-1603
  clinical characteristics, 1604t
  clinical presentation, 1603
  diagnostic criteria, 1602b
  pathobiology, 1602-1603

Juvenile myelomonocytic leukemia (JMML) *(Continued)*
  peripheral blood samples, 1396f
  prognosis, 1603
  treatment, 1603
Juvenile nasopharyngeal angiofibroma, 2244f
Juvenile pilocytic astrocytoma (posterior fossa pilocytic astrocytoma), 1807f
Juvenile rheumatoid arthritis (JRA), ALL (relationship), 1538
Juvenile xanthrogranuloma, 2110

K

Kala-azar (visceral leishmaniasis), 1213-1214
Kaplan-Meier event-free survival curves (neuroblastoma), 1698f
Kaposiform hemangioendothelioma, 1967
  tumors, irregular nests, 1967f
Kaposi sarcoma (KS), 1968
  monomorphic spindle cells, fascicles, 1968f
Karyotype
  clear cell sarcoma karyotype, 1369f
  complex karyotype, 1346
  malignant germ cell tumor karyotype, 1377f
  normal karyotype, presence, 1566-1567
Karyotyping, 1337-1347
  aberrations, detection (technical limitations), 1346-1347
Kasabach-Merritt syndrome, 63, 1097-1098
  evidence, 1098b
  infant example, 1098f
K^+,Cl^- cotransporter, 508-509
Kell alloimmunization, 69
Kell antibodies, impact, 97
Kell glycoprotein, 477
Kell system, 1132
Kernicterus, 109-110
Kernicterus, signs (development), 118-119
Ketamine, usage, 2364
Kidd glycoprotein, 477
Kidd system, 1133
Kidneys
  band 3, 472
  clear cell sarcoma. *See* Clear cell sarcoma of the kidney.
  desmoplastic round-cell tumor, 2203f
  diffuse renal enlargement/infiltration, 2204f
  folate, presence, 312
  malignant rhabdoid tumor. *See* Malignant rhabdoid tumor of the kidney.
  primitive neuroectodermal tumor of kidney, 1726
  rhabdoid tumors, 2199
  synovial sarcoma, 1726
KIF1B, 1684
Killer cell immunoglobulin-like receptor (KIR), genomic map, 1464f
Kinlen hypothesis, 1246
KIT mutations, 1398
Kit protooncogene, 36
KIT receptor, 18, 26
Kleihauer, acid elution technique, 80f
Klinefelter syndrome, 2069
Knee, lobular mass (MRI), 2224f
Krabbe disease, 944-945
  infantile Krabbe disease, 944
  late onset Krabbe disease, 944-945
KTLS cells, transplantation, 8-9
Kx protein, 477

L

Labile factor (factor V), 974-975
Labor, anesthesia (impact), 1253
Laboratory TLS (LTLS), Hande-Garrow definition, 2284b
Lactate dehydrogenase (LDH) deficiency, 603
  biochemistry, 603
  clinical manifestations, 603
  genetics, 603
Langerhans cell histiocytosis (LCH), 2102-2110
  bones, involvement, 2105-2106
  central nervous system (CNS), relationship, 2106-2107
  clinical features, 2103-2104
  comparison, 2120t
  diagnostic evaluation, 2104
  histopathologic features, 2104f
  incidence, 2102-2103
  long-term consequences, 2109-2110
  management, 2104-2109
  multisystem LCH (MS-LCH), 2103
    treatment, 2108-2109
  non-Langerhans cell histiocytoses, 2110-2111
  pathology, 2103-2104
  reactivation, 2109
  refractory LCH, 2109
  results, 2108f
  risk organs, 2107-2108
  single-system LCH (SS-LCH), 2103
  sites, 2107
  skin, involvement, 2106
  therapeutic options, overview, 2110
  unifocal Langerhans cell histiocytosis, MRI scans, 2105f
Laparoscopic splenectomy, 543
Large-cell medulloblastoma, 1841
Large intestine, diseases, 1188
Large platelets, impact, 142-143
Large-specimen biopsies, 1497-1498
Laser ablation, 2245-2246
Late effects. *See* Childhood cancer
  organ system late effects, 2410-2423
Late onset CEP, 395
Late-onset erythropoietic protoporphyria, 405
Late onset Krabbe disease, 944-945
  treatment, 945
Late-onset X-linked protoporphyria, 406
Lateral diffusion, 461
Lead
  biologic effects, 377-379
  hematologic effects, 377-379
  poisoning, treatment, 379-380
  sources, 377
  toxicity, 377-380
Lectin pathway complement components, deficiency, 918
Left deltoid, T2-bright lesions, 2225f
Left flank pain/hematuria, ultrasound, 2202f
Left frontal dysembryoplastic neuroepithelial tumors (DNETs), 1821f
Left leg

  geographic distribution, 716f
  globin chain stability, mutations (impact), 732-733
  globin mRNA, conserved features, 717-719
  globin structural variants, interaction, 766-767
  haplotype analysis, 733-735
  hemoglobinopathies, 733, 766-767
  heterozygotes, hereditary persistence (phenotypes), 735t
  intermedia, iron overload, 763
  locus control regions, 720-721
  major, birth rate (decrease), 767f
  mRNA translation initiation, mutations (impact), 730

Thalassemia *(Continued)*
  mutations, 731f
    classes, impact, 724-733
    diversity, 745-767
    introns, impact, 730f
    origin, malaria (impact), 723-724
  point mutations, impact, 725t-727t
  polyadenylation
    defects, 730
    occurrence, 731f
  premature termination (nonsense) mutations, 730-731
  prenatal diagnosis, 767-768
  proximal regulatory sequences, 719-720
  red cells, phospholipid asymmetry (loss), 352-355
  RNA cleavage, 730
    occurrence, 731f
  RNA processing defects, 728
  sequences/introns, 717
  silent deletions, 738-739
  splice consensus sequences (alteration), mutations (impact), 728
  splice junctions (alteration), mutations (impact), 728
  splice site creation, mutations (impact), 730f
  splicing
    abnormality, examples, 729f
    consensus sequences, alteration, 729f
  termination codon mutations, 731-732
  trait
    differential diagnosis, 751-752
    hematologic parameters, 751t
  transcription factors, 719-720
  transfusion therapy, 1138
Therapeutic apheresis, 1154
  indications, 1157t-1158t
Therapeutic drug monitoring, 1441
Therapeutic index
  improvement, strategies, 1439-1443
  pathophysiologic status, 1440-1441
Therapeutic plasma exchange (TPE), 421
Therapeutic radiation, goal, 1486-1487
Therapy-related acute myeloid leukemia, 1394
Therapy-related myelodysplastic syndrome (MDS), hypersegmented granulocyte (presence), 1395f
Thermal ablation, 2244-2246
Thermal injury, 1200-1201
Thiamine-responsive megaloblastic anemia (TRMA) (Rogers syndrome), 341, 373
Thiopurine methyltransferase (TPMT), 1540-1541
  polymorphisms, 1427f
Thiopurines, 1423-1426
Third World, anemia (prevalence/causes), 1204-1205
13-cis-retinoic acid, impact, 1703f
3-phosphoglyceride dehydrogenase deficiency, 342
Thrombastenia, 1012-1014
  Glanzmann thrombasthenia, 1011-1015
Thrombin
  formation, catalysis, 967f
  illustration, 981f
  impact, 132f
Thrombin-antithrombin (TAT) complexes, endogenous plasma concentrations, 2525t
Thrombin clotting time (TCT), determination, 133-134

Thrombin generation assays (TGAs), 1008
Thrombin time (TT), 1006
Thrombocytopenia, 1076-1099, 1168, 1180
  abnormalities, 1024
  autoantibody-mediated thrombocytopenia, 1144
  causes, 1092b
    platelet production, decrease (impact), 1098-1099
  clotting abnormalities, relationship, 1172
  congenital dyserythropoiesis, association, 243
  differential diagnosis, 1077b
  hypersplenism, impact, 1078
  immune-mediated thrombocytopenia, 1144
  immune thrombocytopenia, 139, 1078-1079
  inherited thrombocytopenia, 247-250
  laboratory artifact/sequestration, 1077-1078
  lymphoproliferative/autoimmune disorders, presence, 1087-1088
  macrothrombocytes, association, 1025-1026
  microthrombocytes, association, 1026
  nursing care, 2303-2304
  platelet destruction, increase (impact), 1078-1098
  pregnancy, relationship, 1198
Thrombocytopenia, differential diagnosis, 41-42
Thrombocytopenia with absent radii (TAR), 142, 250-251, 1024
  clinical management, 251
  clinical manifestations, 250-251
  differential diagnosis, 251
  example, 251f
  genetic characteristics, 251
Thrombocytosis, 1099
  causes
    childhood, 1099b
    children, 1610b
Thromboelastography (TEG), 1008
Thromboembolic (TE) complication, risk (increase), 49-50
Thromboembolic (TE) diseases, 542-543
  acquired thromboembolic (TE) disease, 1110-1123
Thrombolysis, 994-995
Thrombolytics, 1115
Thrombolytic therapy, 148
Thrombomodulin, 977-978
Thrombophilia
  risk factors, 1119
  traits/conditions, VTE risk estimates, 1112t
Thrombophilia, management, 450
Thrombopoiesis, representation, 15f
Thrombopoiesis-stimulating agents, usage, 1086
Thrombopoietin (TPO), 132
Thrombopoietin-Mpl axis, disorders, 1023-1024
Thrombopoietin (Tpo) (TPO), 15-17
  circulating levels, increase, 26
  cloning, 41
  discovery, 41
  function, study, 41
  genes
    evolution, 22
    expression, regulation, 26
  megakaryocytopoiesis, relationship, 41-42

Thrombopoietin (Tpo) (TPO) *(Continued)*
  mimetics, usage, 48
  production, 41
  TPO R, 26-27
  in vitro activity, 43
Thrombosis, 141, 542-543, 994-995
  acute thrombosis, long-term management, 1071-1073
  heparin-induced thrombosis, 1091-1092
  pregnancy, relationship, 1198
Thrombotic microangiopathic disorders, 1092-1097
Thrombotic thrombocytopenia purpura (TTP), 1092-1095
  clinical features, 1094
  clinical manifestations, 1093t
  diagnosis, 1094
  immunohistochemistry, 1093
  pathogenesis, 1094f
  pathophysiology, 1093-1094
  treatment, 1094-1095
Thrombus stability, feed-forward amplification pathways (involvement), 957-959
Thymic masses, 2171-2173
Thymic stromal thymopoietin (TSLOP), 15
Thymocytes
  negative selection, 862
  positive selection, 862
Thymolipomas, 2173
  chest x-ray, 2174-2177
Thymoma, 2171-2173
Thymus-dependent B-cell responses, 867
Thymus, T-cell receptor rearrangement/selection, 860-862
Thyroid cancer, 2406-2407
  differentiation, 1519-1520
Thyroid carcinomas, 1376, 2126-2129
  clinical presentation, 2127
  epidemiology, 2126
  follow-up observation, 2129
  incidence, 2127f
  lymph node dissection, 2128
  molecular pathology, 2126-2127
  outcomes, 2127-2129
  pathology, 2126-2127
  prognostic factors, 2127
  radioactive iodine, use, 2128-2129
  staging, 2127
  surgery, 2127-2128
  survival rates, 2128f
  targeted therapies, 2129
  treatment, 2127-2129
Thyroid disorders, 2416-2417
Thyroid gland, disorders, 1190-1191
Thyroid hormone, hematologic effects, 1190t
Thyroid tumors, 2167-2168
Thyroid ultrasound, 2168f
Tibial bone marrow cell populations, 2516t-2517t
Tibia, osteosynthesis (radiographic appearance), 1514f
TINF2 mutation, 211-212, 216, 218
Tissue factor (TF)
  coagulation factor III, 976-977
  composition, 977f
  pathway inhibitor (extrinsic pathway inhibitor) (lipoprotein-associated coagulation inhibitor), 979
  TF-initiated blood coagulation, two-compartment model (schema), 968f
  tissue thromboplastin Cd142, 976-977
Tissue fibrosis, 995
Tissue plasminogen activator (tPA), 987f, 988
Tissues
  adhesion/migration, 785-788
  carbon dioxide, conversion, 472f
  injury, infection response, 782f
  leukocyte adhesion/migration, 785-788
Tissue thromboplastin Cd142 (tissue factor), 976-977
T-lineage ALL, DNA methylation patterns (aberration), 1390
TLX3(HOX11L2) homeobox genes, 1654-1655
TLX(HOX11) homeobox genes, 1654-1655
T lymphocytes
  absolute numbers, 2514t-2515t
  characteristics, 853f
Tobacco smoking (parents), 1252
Toll-like receptor (TLR) signaling, defects, 902
Topotecan, usage, 1934
Topotecan, vinorelbine, thiotepa, dexamethasone, and gemicitabine (TVTG), 1587
Toronto Extremity Salvage Score (TESS), 1516-1517
Total B cells, percentages/absolute counts, 2510t
Total bilirubin measurement, 109
Total-body irradiation (TBI), 256
  busulfan, contrast, 257
Total homocysteine assay (tHcy), 326
Total homocysteine percentile distributions, 2504t
Total iron-binding capacity, 2502t-2503t
Total serum bilirubin measurements, 107-109
Total T cells, absolute counts, 2512t-2513t
Toxicity
  acceptability, 1303-1304
  reduction, 1304
Toxins
  insults, 1199-1201
  usage, 163-164
TP53 gene, constitutional mutations, 1730
TP53 mutations, 1399
TPM4-ALK fusion oncogene transcripts, RT-PCR demonstration, 1354f
Trabecular architecture, loss, 2226f
Trace metals, deficiency, 764
Tracheal areas
  peak expiratory flow rate (PEFR), relationship, 1491f
  symptoms, correlation, 1491f
Tracheal deviation, chest x-ray, 2170f
Tracheobronchial tree masses, 2174-2177
Tracks
  empiric track, 1307
  genetics tracks, 1306
  host tracks, 1306-1307, 1319
  synthetic lethal track, 1307
Traffic, exposure, 1251
Transarterial chemoembolization (TACE), 2242-2243
Transarterial radioembolization (TARE), 2243
Transcobalamin deficiency, 338
Transcobalamin I (haptocorrin) deficiency, 338-339
Transcriptional regulators, 1531-1532
Transcription factors, 719-720
  defects, 1024-1025
  encoding, HOX genes (usage), 35
  erythropoiesis, relationship, 38
  GATA family, 34
Transcription factors *(Continued)*
  genes, chromosomal rearrangements, 1358-1360
  hematopoiesis, relationship, 34-35
    requirements, 10f
  myelopoiesis, relationship, 40
  pediatric cancer, relationship, 1328-1330
  thalassemia, 719-720
  tumor suppressors, 1655-1656
Transcutaneous bilirubinometry, 109
Transependymal flow, axial fluid-attenuated inversion recovery image, 1793f
Transferrin
  cycle, 349-351
  endocytotic transferrin cycle, 350f
  non-transferrin-bound iron uptake, 351
  receptor, 354
  saturation, 2502t-2503t
  soluble transferrin receptors, 354-355
Transforming growth factor beta (TGF-β) negative regulator, 20
Transforming growth factor beta (TGF-β) gene family, 16
Transfusion
  acute hemolytic transfusion reactions, 1141
  allergic reactions, 1140-1141
  blood selection, 1136-1139
  blood transfusion, problems, 1223
  chronic transfusion
    red blood cell exchange, 1159
    therapy, 1128-1129
  component assessment, 1151-1152
  granulocytic transfusions, 1149
  hemolytic transfusion reactions, delay, 1141
  immunologic considerations, 1129-1135
  indications, 1128-1129
  platelet transfusion, 1143-1149
  post-transfusion platelet counts, decrease, 1147t
  reactions, management guidelines, 1140t
  red blood cell transfusions, 1128-1142
  sickle cell anemia, relationship, 708-709
  support, 262
  thalassemia, relationship, 1138
  therapy, 419-420
Transfusional GVHD, 166
Transfusion-associated acute lung injury, 1141
Transfusion-associated circulatory overload, 1141
Transfusion-associated gut injury, 1141
Transfusion-transmitted diseases, 1141-1142
  risk, estimation, 1142t
Transient abnormal myelopoiesis (TAM), 1397-1398
  Down syndrome TAM, 1396f
Transient erythroblastopenia of childhood (TEC), 179-180, 235-236
Transient hypogammaglobulinemia of infancy (THI), 913
Transient myeloproliferative disorder (TMD), 68
Translocations
  BCR-ABL1 translocations, 1385
  breakpoints, 1345f, 1989f
  chromosomal translocations
    biologic consequences, 1358-1363
    causes/predisposing factors, 1356-1358
  core-binding factor complex, involvement, 1562-1564

Translocations *(Continued)*
  E2A gene translocations, 1385
  mixed-lineage leukemia (MLL)
    gene translocations, 1393
    translocations, 1385-1387
  NUP98 translocations, 1394
  TEL-AML1 translocations, 1385
  Xp11/6p21 translocations, 1373-1374
Transmembrane cofactors, 977f
Transplacentally acquired infections, diagnostic features, 64t
Transplantation, 1162
  immunosuppression, contrast, 176-177
Transplanted cell dose, differences, 1150t
Transport channel, usage, 472-473
Trauma, G6PD deficiency (impact), 627
Traumatic fetal hemorrhage, 59
Treasure Box prototype, 2477f
Treatment
  cessation, patient/family support, 2308-2309
  locations, patient care, 2307-2308
  transitioning, emotional impact, 2308
Treatment-associated acute myelogenous leukemia
  metaphase spectral karyotype, 1350f
  Southern blot analysis, 1347f
Treatment planning, target volumes, 1479f
Treatment-related acute myelogenous leukemia, MLL gene amplification, 1348f
Trilateral retinoblastoma, 1771, 1775-1776
Triomab antibodies (TriomAbs), binding, 1458f
Triose phosphate isomerase (TPI) deficiency, 591-593
  biochemistry, 591-592
  clinical manifestations, 591
  genetics, 592
  inheritance, 592
  therapy, 592-593
Triphasic Wilms tumor, 1719
TRKB inhibitors, 1711
Tropical eosinophilia, 1217-1218
Tropics
  hemostatic failure, systemic disease manifestation, 1219-1220
  infections, hematologic changes (association), 1205-1217
  malabsorption, hematologic aspects, 1218-1219
Tropomodulin, 493
Tropomodulin-1 (TMod1), 493
Tropomyosin (TM), 492-493
  gene structure, 493f
TRPC6 channel, 509
True rosettes, presence, 1851-1852
Trypanosoma cruzi (blood), 1215f
Trypanosomiasis, 1214-1215
  African trypanosomiasis, 1215
  American trypanosomiasis (Chagas disease), 1214-1215
  susceptibility, 908
Tryptic domains, 485
Tryptic maps, 553
Tryptophan-Serine-X-Tryptophan-Serine (WSXWS), 15, 26-27
  motif, 28f
T state
  deoxy T state (PDB 2DN2), 642f
  quaternary structure, hydrogen bonding interactions, 644t
Tuberous sclerosis, 1787
  Rapamycin, mammalian target, 1324
Tumor antigens (TAs), 1449f
  binding, 1458f
  lineage-specific tumor antigens, 1453
Tumor cells
  destruction, antibody-mediated mechanisms, 1449f
  growth, predictability (absence), 1345-1346
  impact, 260-261
  lysis, 1449f
  requirement, 1337-1345
Tumorigenesis
  MYCN, role, 1681
  myogenic pathways (rhabdomyosarcoma), 1917-1919
Tumor lysis syndrome (TLS), 2281-2289
  acute renal failure, 2289
  assessment, algorithm, 2285f

Tyrosine-threonine-arginine-phenylalanine amino acid motif, 349f
Tyrosine transphorphorylation, 29-31

U

Ubiruitination sites, 485
UGT1A1 promoter region, UGT1A1 activity (increase), 115
Ultrasound, 2148-2149
  assessment, 88-89
Ultraviolet-visible wavelength light spectroscopy, usage, 657
Umbilical cord blood, erythroblast/leukocyte counts, 2486t
Umbilical vein, intraabdominal vein (real-time two-dimensional ultrasound view), 91f
Umbilical vessels, intrapartum hemorrhage, 60
Unclassified intratubular germ cell neoplasia, 2060-2061
Unclassified lymphoproliferative disease, adenopathy (presence), 2191f
Unconjugated antibodies, 1457-1458
Unconjugated bilirubin (UBIL), 105
  fractions, 107-109
    elevation, impact, 119-121
Unconjugated hyperbilirubinemia
  causes, 118
  disorders, comparison, 113t
  exchange transfusion, 121
  feeding strategies, 123
  management/treatment, 118-123
  pharmacotherapy, 122-123
  phototherapy, 121
  toxicity, 109-110
Undifferentiated pleomorphic sarcoma, 1980-1981
Undifferentiated round cell sarcoma, 1980-1981
Undifferentiated spindle cell sarcoma, 1980-1981
Undifferentiated tumors, 1980-1981
Unicortical plate, usage, 1515f
Unilateral retinoblastoma, 1766-1768
  management algorithms, 1767f
Unincubated osmotic fragility, correlation, 522f
Uniparental disomy (UPD), 190f
United Kingdom Children's Cancer Group (UKCCG), 1499-1500
Unpaired non-alpha chains, tetramer, 66
Unresectable hepatoblastoma, 2150f
Unusually large VWF (ULVWF), 131, 133
Upper thoracic paraspinal neuroblastoma, 2167f
Uracil nucleoside glycosylase (UNG), mutations, 914-915
Uremia, 1100, 2289
  impact, 1186f
Ureter compression, rhabdoid tumor (impact), 2248f
Uric acid, breakdown product, 2283f
Uridine diphosphate glucuronic acid (UDPGA), 105
Uridine diphosphate glucuronosyltransferase-1 gene, structure, 105f
Uridine diphosphate glucuronosyltransferase isozymes, 114-115
Uridine diphosphate N-acetyl glucosamine (UDPNAG), 105
Urinary bladder carcinoma, 2139-2140
Urine porphyrin profile, 399f
Urokinase (uPA), 987f, 988-989
Urokinase-mediated plasmin generation, 993-994
Urokinase receptor (uPAR), 990
Uroporphyrinogen decarboxylase (URO-D), 395-400
  crystal structure, 396f
  reaction, catalysis, 396f
Uroporphyrinogen III (urogen III), binding, 396f
Uroporphyrinogen III synthase (URO3-S), 393-395
  reaction, catalysis, 393f

V

Vaccines
  dendritic-cell vaccines, 1454
  DNA vaccines, 1455
  idiotype vaccines, 1455
  peptide-based vaccines, 1454-1455
  tumor vaccines, 1453-1455
  whole-cell vaccines, 1455
Vacuolated normoblasts, presence, 1199f
Vaginal delivery, cord blood (hematologic values), 2485t
Vaginal tumors (rhabdomyosarcoma), 1941
Vagina, tumors, 2141-2142
Valvular disease, 2413
Van den Bergh's test, 107-109
Variegate porphyria (VP), 402-403
  clinical manifestations, 403
  frequency, 402
  laboratory diagnosis, 403
  pathogenesis, 403
  treatment, 403
Vasa previa, 59
Vascular access, 1155
Vascular cell adhesion molecule 1 (VCAM-1), binding, 4-5
Vascular endothelium, anticoagulant/antithrombotic components, 955f
Vascular malformations, 141
Vascular purpuras, 1101
  childhood, 1101b
Vascular tumors, 1966-1968
Vasculitis, 1170
Veins, bilateral upper/lower extremity venograms, 2247f
Velocardiofacial syndrome, 143
Vena cava filters, 1116
Venoms, 1201
Veno-occlusive disease (VOD), 264-265
Veno-occlusive disease with immunodeficiency (VODI) syndrome, 896
Venous access, 2246
  difficulty, 2247f
Venous catheter-related thrombosis, 145
Venous thromboembolism (VTE), 1111-1118
  anticoagulants, usage, 1115
  anticoagulation
    extension, 1114
    initiation, 1114
  children, Virchow's triad (application), 1112f
  clinical presentation, 1112-1113
  epidemiology, 1111
  etiology, 1111-1112
  long-term outcomes, 1116-1117
  outcomes, 1116-1118
    anatomic site, 1117-1118
    children, 1117t
  prognostic indicators, 1118
  risk estimates, 1112t
  therapeutic agents, usage, 1115-1116
  therapy, duration, 1114-1115
  thrombolytics, usage, 1115
  treatment, 1113-1116
  vena cava filters, 1116
Ventricles, enlargement (axial fluid-attenuated inversion recovery image), 1793f
Very late antigen 4 (VLA-4) integrin, binding, 4-5
Very low birth weight infants, red blood cell parameters, 71t
Vesicant extravasation, 2289-2290
Vesiculation
  formation, 510
  impact, 528-529
Vessel wall, antithrombotic components, 954
Vincristine, 1430
  usage, 2002-2005, 2047
Vincristine, actinomycin-D, doxorubicin, and cyclophosphamide (VACA), 2002-2005
  dose-intensified VACA/IE regimens, 2006-2007
  VACA-based therapy, 2005-2006
Vincristine/dactinomycin (actinomycin D)/cyclophosphamide (VAC) chemotherapy, evolution, 1933t
Viral hemorrhagic fevers, 1220
Viral hepatitis (children), 1891-1892
Viral infections, 1175-1181, 2258-2259
  control, allogeneic adoptive T-cell therapy (usage), 1470
Virchow's triad, application, 1112f
Viruses, impact, 165
Visceral leishmaniasis (Kala-azar), 1213-1214
Vitamin B_6 percentile distributions, 2504t
Vitamin B_{12} (cobalamin), 314-319
  deficiency, occurrence, 69
  percentile distributions, 2504t
Vitamin E (alpha-tocopherol)
  deficiency, 763-764
  plasma levels, 2506t
Vitamin K (VK), 1254
Vitamin K (VK) deficiency, 1107-1108
  clinical presentation, 1107-1108
  impact, 137-138
  laboratory diagnosis, 138, 1108
  prevention, 1108
  treatment, 1108
Vitamin K-dependent bleeding (VKDB), 137-138
Vitamin K-dependent complexes, 966f
Vitamin K-dependent factors, 130-131
Vitamin K-dependent glutamic carboxylation. occurrence, 130

Vitamin K-dependent proteins
  family, 969-974
  schematic representation, 971f
Vitamins, content assays, 324-325
Vitamin supplements, usage, 1252
VITROS, 107-109
Vomiting, 2369-2381
  causes, 2380
  chemotherapy-induced nausea and vomiting, 2370-2378
  delayed vomiting, 2378
  disease-related vomiting, 2380
  nursing care, 2304
  opioid-induced nausea and vomiting, 2380
  pathophysiology, 2369-2370
  postoperative vomiting, 2379-2380
  predictors, 2373
  radiation-induced nausea/vomiting, 2378-2379
von Dungern, Emil (experiments), 82
von Hippel-Lindau (VHL) disease, 1823
  enhanced images, 2165f
Von Hippel-Lindau (VHL) syndrome, 1287-1288
  genetics, 1287
  incidence, 1287
  tumor risks/surveillance, 1287-1288
von Hippel-Lindau (VHL) tumor suppressor, binding, 25-26
von Willebrand disease (VWD), 139, 1039-1053
  acquired von Willebrand disease, 1052
    mechanisms, 1053f
  classification, 1047-1049
  clinical manifestations, 1046-1049
  demographics/classification, 1042
  desmopressin, 1049-1050
  diagnosis, laboratory evaluation (algorithm), 1049f
  genetics, 1041-1042
  laboratory evaluation, 1042-1046
  medical history, 1046-1049
  pathophysiology, 1040-1041
  platelet-type von Willebrand disease, 1017-1019
  qualitative type 2 variants, disease mechanism, 1045f
  subtyping, absence, 1052-1053
  treatment
    comments, 1053
    fundamentals, 1049-1053
  type 1C von Willebrand disease, 1048
  type 1 von Willebrand disease, 1047-1048
    desmopressin, administration, 1052f
    mechanisms, 1044f
  type 2A von Willebrand disease, 1048
  type 2B von Willebrand disease, 1048
  type 2M von Willebrand disease, 1048-1049
  type 2N von Willebrand disease, 1048
  type 2 variant types, 1048-1049
  type 3 von Willebrand disease, 1048
    concentrate, infusion, 1051f
    mechanisms, 1044f
  types, 1043f
  type-specific treatment, 1050-1052
  variant forms, 1047f
  variant subtype mutation location, protein structure (relationship), 1041f
von Willebrand factor (VWF), 131
  antigen, 1042
  assays, clinical disorders (impact), 1046
  collagen-binding assay, 1044
  concentrates, 1050
  gene sequencing, 1046
  laboratory assays, variables (impact), 1046
  multimeric analysis, 1045f
  multimers, 1044-1046
    autoradiogram, 1093f
  plasma von Willebrand factor, binding, 1040f
  reference intervals, 2524t
  release, 131
  ristocetin cofactor activity assay, 1042-1043
  type 1 von Willebrand disease, contrast, 1042
von Willebrand factor propeptide (VWFpp), 1046
von Willebrand factor (VWF) (ristocetin cofactor), 976

W

Warm-reactive autoantibodies, 416-417
Warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM) syndrome, 774-775, 806, 902-903
  CXCR4 receptor, 783-784
W bone marrow, transplantation, 36
Weak opioids, 2357-2358
Wegener granulomatosis, 1170
West Nile Virus (WNV), 1142
White blood cells (WBCs), 1186
  alcohol, relationship, 1200
  count, clinical guidelines, 2282b
  diabetes mellitus, 1192
  disturbances, 1171-1172
  mean values, 2496t
  reference intervals, 2496t
  reference ranges, 2496t
White matter tracts, components, 1791
White spotting (W) mutations, 36
Whole blood-derived platelets, 1146
Whole blood fibrin formation, schematic representation, 982f
Whole-body fluorodeoxyglucose positron emission tomography (FDG-PET) scan, 1995f
Whole-cell vaccines, 1455
Whole exome sequencing, workflow, 1265f
Whole genome sequencing, 1263-1264
Whole transcriptome shotgun sequencing (RNA-Seq), 1264
Wild-type ALK receptor signaling, 1682
Wild-type EWS protein, 1986
Williams factor (high-molecular-weight Kininogen), 978-979
Wilms tumor (WT) (nephroblastoma), 1284, 1374-1375, 1499-1501, 2196-2198
  anaplastic Wilms tumor, 1735-1736
    example, 1717f
  beta-catenin (CTNNB1), 1727-1728
  bilateral Wilms tumor, 1736
    CT evaluation, 2199f
  blastemal patterns, 1716
  chemotherapy, 1733-1735
  childhood (National Wilms Tumor Study Group staging), 2197t
  clinical presentation, 1730-1731
Wilms tumor (WT) (nephroblastoma) *(Continued)*
  congenital mesoblastic nephroma, contrast, 1722
  cystic variants, 1715-1716
  diagnostic evaluation, 1730-1731
  differential diagnosis, 1719
  diffuse anaplasia, 1717
  epidemiology, 1726-1727
  epithelial predominant Wilms tumor, papillary renal cell carcinoma (contrast), 1719
  focal anaplasia, 1717
  genes, association, 1728t
  genetics, 1283, 1727-1729
  gross features, 1715
  histology
    anaplasia, impact, 1717
    diffuse blastemal pattern, 1716f
    triphasic pattern, 1716f
  IGF2, 1729
  immunohistochemical studies, 1718
  incidence, 1283
  left renal Wilms tumor, ultrasound, 2198f
  loci, association, 1728t
  malignancy, 1485
  malignant rhabdoid tumor of the kidney (MRT), contrast, 1723
  metastatic Wilms tumor, 2181f
  microscopic features, 1716-1717
  molecular biology, 1727-1729
  National Wilms tumor studies, findings, 1732t
  nephrogenic rests/nephroblastomatosis, 1718-1719
  patient outcome (NWTS-5), loss of heterozygosity (effect), 1733t
  pulmonary metastases, 1521-1522
  radiation therapy, 1731-1733
  recurrent Wilms tumor, 1736-1738
  SIOP postchemotherapy histologic classification system, 1717-1718
  stromal patterns, 1717
  subsets (definition), genetic/epigenetic features (usage), 1729-1730
  surgery, 1731
  TP53 gene, constitutional mutations, 1730
  treatment, 1731-1735
    late effects, 1737-1738
  triphasic histology, 1374f
  triphasic Wilms tumor, 1719
  tumor risks/surveillance, 1283-1284
  ultrastructural studies, 1718
  WT1 regions, 1370f, 1727
  WT1-related tumor predisposition syndromes, 1283-1284
    clinical/genetic features, 1284t
  WTX (AMER1/FAM123B), 1728-1729
Wilson disease, hematologic aspects, 376-377
Wintrobe, M.M., 299
Wiskott-Aldrich syndrome (WAS), 142, 282, 898-899
  protein-interacting protein deficiency, 899
Wnt, 18-19
  pathway, 2037
  signals, passage, 36-37
Wnt 3A, overexpression, 18-19
Wnts, ligand family, 1788f
Wolman disease, 941
Wong-Baker Scale, 2352-2353

Wood dust, exposure, 1251
Wound healing, 995
WTX (AMER1/FAM123B), 1728-1729
WWOX, 2037

X

Xenopus species
  BMP-4, importance, 16
  GATA2 expression, 34
Xenopus systems, HSC production, 19
Xerocytosis, 537, 560-573
  syndromes, features, 561t
X-linked agammaglobulinemia (XLA), 909
X-linked alpha-thalassemia, mental retardation syndrome (association), 743-744
X-linked anemia with severe thrombocytopenia, 1024-1025
X-linked dyskeratosis congenita, 209-210
  peripheral blood smear, 371f
X-linked immunodeficiency, 913-914
X-linked lymphoproliferative (XLP) disease, 906-907
X-linked protoporphyria (XLPP), 405-406
  clinical manifestations, 406
  late-onset X-linked protoporphyria, 406
  pathogenesis, 406
  treatment, 406
X-linked severe combined immunodeficiency, 891-892
X-linked sideroblastic anemia (XLSA), 371-373
X-linked sideroblastic anemia with ataxia (XLSA/A), 373
X-linked thrombocytopenia, 142
Xp11.2 translocation renal cell carcinomas, 1723-1725, 1724f
  TFE3 immunohistochemistry, 1724f

Y

Yolk sac erythropoiesis, initiation, 83
Yolk sac tumor (YST), 2063-2064, 2070f
  histopathology, 2063
  myxoid stroma, 2063f
  ovarian yolk sac tumor, 2064
  testicular yolk sac tumor, 2063-2064
Young children, tumor management issues, 1866-1869

Z

ZAP-70 deficiency, 894
Zebrafish systems, HSC production, 19
Zeta potential, bridging, 414f
Zipperlike dimerization, alpha/beta chains (side-to-side interactions), 482
ZUS-ANK, binding, 480f
Zymogen plasminogen, conversion, 985f
